October 2018
To my parents and sister
Acknowledgments

I would like to begin by giving a special word of appreciation to Claude Cochet from BNP Paribas for all his help in the development of this work, providing not only a crucial insider knowledge but also some truly useful advice, and for always finding some time in his busy schedule to guide me.

I would also like to thank my two supervisors, Professor Cláudia Nunes and Professor Rui Dilão, without whom this thesis would have been unimaginable. Professor Cláudia not only introduced me to this amazing field of Mathematical Finance but also contributed with a much-needed support throughout the entire development of this work. Professor Rui, being an unfathomable source of knowledge in the most varied fields, provided many valuable insights, particularly on the more technical sections, but also an important guidance.

To my friends, who accompanied me in these last 5 arduous years through difficult assignments, impossible exams, and lost hours of sleep, but also in the great times joking around and relaxing, a sincere thank you.

Finally, this work would have never been possible without the unconditional support of my family and my girlfriend. Only their confidence in me and their many sacrifices enabled me to reach this far.
Resumo

Volatilidade é um dos tópicos mais importantes em matemática financeira, graças não só ao seu impacto nos preços de opções, mas também à sua indefinição. Nesta dissertação estudamos alguns dos modelos mais utilizados para prever esta variável, nomeadamente o modelo de volatilidade local de Dupire, bem como os modelos de volatilidade estocástica de Heston e Static/Dynamic SABR. Treinamos estes modelos com dados de volatilidade implícita de algumas opções, tornando-os capazes de replicar o comportamento do mercado. Descobrimos que, quando apenas são usadas opções com uma única maturidade, o modelo Static SABR é o que melhor se ajusta aos dados, enquanto que quando se usam múltiplas maturidades, o modelo Heston supera o Dynamic SABR. Todos estes modelos têm um desempenho vastamente superior ao do modelo de volatilidade constante, assumido em Black-Scholes. De seguida, os modelos treinados são usados para avaliar opções europeias e de barreira, com o método de avaliação numérica de Monte Carlo, com o qual somos capazes de prever com precisão as volatilidades implícitas para opções “near-the-money”, falhando para opções de compra europeias “deep in-the-money”.

Palavras-chave: Volatilidade, Avaliação de Opções, Dupire, Heston, Static SABR, Dynamic SABR
Abstract

Volatility is one of the most important subjects in all of quantitative finance, due not only to its impact on the prices of options but also to its elusiveness. In this thesis we study some of the models most used to forecast this variable, namely Dupire’s local volatility as well as Heston and Static/Dynamic SABR stochastic volatility models. We train these models with some options’ implied volatility data, making them able to replicate real market behavior. We find that, when dealing with options with a single maturity, the Static SABR model is the one that best fits the data, while with multiple maturities, the Heston model outperforms Dynamic SABR. All these models vastly outperform the constant volatility model, assumed in Black-Scholes. We then use these trained models to price European and Barrier options with the Monte Carlo numerical pricing method, which is able to accurately predict implied volatilities for near-the-money options, failing for deep in-the-money European call options.

$imp,i$  Implied (related to volatility).
Chapter 1

Introduction

1.1 Mathematical Finance

Mathematical finance, also known as quantitative finance, is a field of applied mathematics focused on the modeling of financial instruments. It is rather difficult to overestimate its importance since it is heavily used by investors and investment banks in everyday transactions. In recent decades, this field suffered a complete paradigm shift, following developments in computer science and new theoretical results that enabled investors to better understand the mechanics of financial markets [Seydel, 2004].

With the colossal sums traded daily in financial markets around the world [World Federation of Exchanges], mathematical finance has become increasingly important and many resources are invested in the research and development of new and better theories and algorithms [Bernstein, 2012].

1.2 Derivatives

Derivatives are currently one of the most studied subjects in all of mathematical finance. In finance, a derivative is simply a contract whose value depends on other simpler financial instruments, known as underlying assets, such as stock prices or interest rates. They can virtually take any form desirable, so long as there are two parties interested in signing it and all government regulations are met.

The importance of derivatives has grown greatly in recent years. In fact, as of June 2017, derivatives were responsible for over $542 trillion worth of trades, in the Over-the-Counter (OTC) market alone [Bank for International Settlements, 2018], having started at only $72 trillion in June 1997, as can be seen in Figure 1.1 (the OTC market refers to all deals signed outside of exchanges). This growth peaked in 2008 but stalled after the global financial crisis due to new government regulations, implemented because of the role of derivatives in market crashes [Financial Times, 2016]. It is easy to see that mishandling derivatives can have disastrous consequences. However, when handled appropriately, derivatives prove to be very powerful tools to investors, as we will see shortly.
1.3 Options

Of all classes of derivatives, in this master thesis we will focus particularly on the most traded type [Hull, 2009]: options.

As the name implies, an option contract grants its buyer the option to buy (in the case of a call type option) or sell (for put options) its underlying asset at a future date, known as the maturity, for a fixed price, known as the strike price. In other words, when signing an option, buyers choose a price at which they want to buy/sell (call/put) some asset and a future date to do this transaction. When this date arrives, if the transaction is favorable to the buyers, they exercise their right to execute it.

The description above pertains only to European options. In this thesis, this type of contracts will be used for model calibration and validation. Other less common types, commonly known as Exotic options, will also be studied in the following sections, with focus on one of the most common types, known as Barrier options, a contract that behaves similarly to European options with the difference that it only becomes valid if the stock price increases past a given threshold at any point until the maturity (assuming a up-and-in Barrier option).

It’s important to emphasize the fact that an option grants its buyer the right to do something. If exercising the option would lead to losses, the buyer can simply decide to let the maturity date pass, allowing the option to expire without further costs. This is indeed the most attractive characteristic of options.

1.3.1 Why Options are Important

Options are very useful tools to all types of investors. In simple terms, there exist two types of investors in the market: hedgers and speculators.

To hedgers (i.e. investors that want to limit their exposure to risk), options provide safety by fixing a minimum future price on their underlying assets - e.g. if hedgers want to protect themselves against a potential future price crash affecting one of their assets, they can buy put type options on that asset.
With these, even if the asset's value does crash, their losses will always be contained because they can exercise the options and sell the asset at the option's higher strike price.

Options are also very useful to speculators (i.e. investors that try to predict future market movements). The lower price of options when compared to their underlying assets grants this type of investors great leveraging capabilities and, with them, access to much higher profits if their predictions prove right. The opposite is also true, and a wrong prediction can equally lead to much greater losses.

Due to all their advantages, and unlike some other types of derivatives, options have a price. Finding the ideal price for an option is a fundamental concern to investors, because knowing their appropriate value can give them a chance to take advantage of under or overpriced options. Finding this price can be very difficult for some option types, however, and though a lot of research has been done towards this goal, a great deal more is still required.

1.4 Volatility

Volatility is a quantity that greatly affects option prices and is used as a parameter in all pricing models. It’s very difficult to define it without the necessary financial background, so we will postpone this description to chapter 3, where we will study it in great detail. For now, we can say that despite its importance, and despite our great efforts to study it, this parameter remains as one of the most elusive phenomena in all of quantitative finance. This elusiveness is mainly caused by our inability not only to predict its future behavior but even actually to accurately measure it, which clearly gives rise to all sorts of problems when using it in any option pricing model.

Due to its importance, many models have been developed throughout the years in an attempt to model this parameter, with varying degrees of success. We will analyze in detail some of the most famous ones in the following chapters, comparing them with one another.

1.5 Repository

In the development of this thesis we used many original code files, written in MATLAB language, from which we obtained the results shown later. They are available in an online repository, which can be accessed freely at https://github.com/Miguel-Ribeiro-IST/Thesis. The code is commented to some degree, to ease the interpretation of all the steps taken.
1.6 Objectives

The goal of this thesis is to study some of the most commonly used models to forecast volatility. We will approach Dupire's local volatility model and Heston, Static/Dynamic SABR stochastic volatility models. We will begin by clearly defining each model and give some insight regarding their advantages and disadvantages.

We will then train all models in a data set of real European option prices, so that they can best replicate real market behavior.

Afterwards, we will implement each trained model on a Monte Carlo numerical pricer, to obtain some simulated option prices. The models will also be compared with one another, to find which is the most suitable in our case.

Finally, the Monte Carlo pricers will be modified to price Barrier options, as an application example of the models.

1.7 Thesis Outline

In chapter 2 we begin by giving some financial background required to understand the posterior sections. We will approach the options' payoff and value functions as well as the Black-Scholes formula and related results.

In chapter 3 we introduce the concept of volatility, implied volatility, and the Greek Vega. We then describe the models to be used, namely Dupire's local volatility model and Heston, Static/Dynamic SABR stochastic volatility models.

Then, in chapter 4 we focus on how each model will be implemented, calibrated and validated. We introduce the CMA-ES optimization algorithm, which we will use to calibrate the models, as well as the Monte Carlo numerical pricer, used to estimate option prices with each calibrated model.

Afterwards, in chapter 5 we comment the results obtained with each of the models and compare them to one another. We also apply these models to price Barrier options. At the end of this chapter we also present some of the pitfalls found during implementation and how we solved them.

Finally, in chapter 6 we give a general overview of the work done and present some of the main conclusions made and possible future work.
Chapter 2

Background

2.1 Option Types

Before completely focusing on the mechanics of options, what influences their prices and how we can try to predict their behavior, we should begin by clearly defining the main option types, their characteristics, as well as their payoff functions. Not only will we approach one of the main types of options - European - but we will also shortly introduce other less common types, commonly referred to as Exotic options, focusing particularly on Barrier options.

2.1.1 European Options

*European options* are the most traded type of option in the OTC market [Investopedia, b]. They are not only extremely useful to investors, but also very simple to study and comparatively easy to price. For all these reasons, they have been the subject of much research and are deeply understood. Furthermore, because of their high availability, they are very useful in model calibration and validation.

As stated before, call and put European options enable their buyers to respectively buy and sell the underlying asset at the maturity for the fixed strike price.

To understand the payoff function of such contracts, we'll use an example. In the case of a European call option, if at the maturity the market price of its underlying asset is greater than the strike, investors can exercise the option and buy the asset for the fixed lower strike price. They can then immediately go to the market and sell the asset for its higher value. Thus, in this case, the payoff of the option would be the difference between the asset’s price and the option’s strike price. On the other hand, if at the maturity the price of the asset decreases past the strike, the investor should let the option expire, since the asset is available in the market for a lower price. In this case, the payoff would be zero. The same reasoning can be made for European put type options, such that the payoff function of both option types
can then be deduced as

\[
\text{Payoff}_{\text{Euro, call}}(K, T) = \max (S(T) - K, 0) ; \quad (2.1a)
\]
\[
\text{Payoff}_{\text{Euro, put}}(K, T) = \max (K - S(T), 0) , \quad (2.1b)
\]

where \( K \) is the option’s strike price and \( S(T) \) is the asset’s price, \( S(t) \), at the maturity, \( T \). These functions are represented in Figure 2.1.

![Payoff functions of European call and put options.](image)

Along with European, \textit{American options} are the other most common type of derivative. While European options dominate the OTC market, their American counterparts are the most traded type of option in exchanges [Investopedia, a]. Because of their great importance, many models have been developed to find the prices of these options [Longstaff and Schwartz, 2001]. American options grant the right to buy/sell (call/put) the underlying asset at any point in time \textit{until the maturity date}. Though they will not be used in this work, they will be briefly mentioned in later sections.

\subsection{Exotic Options}

While European and American options are, by far, the most traded types, \textit{Exotic options} should not be neglected. Exotic options are derivatives that differ from European in terms of the underlying asset or the payoff function [Investopedia, c]. Not only does there exist a great number of Exotic option types, but these are also highly customizable, making this type of derivatives ideal for unconventional investment strategies. Due to their high complexity, these options are only traded in the OTC market, and not in exchanges. We will explore one of the most common types of Exotic options - \textit{Barrier} options - though many others exist.
Barrier Options

A Barrier option behaves similarly to a European option with the difference that it only becomes active (or becomes worthless) if the value of its underlying asset reaches a particular value, called the barrier level, $B$, at any point in time until the option's maturity.

There are four main types of Barrier option:

- **up-and-out**: the asset’s price starts below the barrier (i.e. $S(0) < B$). If it increases past this threshold, the option becomes worthless;

- **down-and-out**: the asset’s price starts above the barrier (i.e. $S(0) > B$). If it decreases past this threshold, the option becomes worthless;

- **up-and-in**: the asset’s price starts below the barrier (i.e. $S(0) < B$). Only if it increases past this threshold does the option become active;

- **down-and-in**: the asset’s price starts above the barrier (i.e. $S(0) > B$). Only if it decreases past this threshold does the option become active.

Because all of the previously described Barrier option types are handled similarly, we can easily adapt the models from one type to another. Thus, for simplicity, we will henceforth assume that all Barrier options are of the up-and-in type.

We now deduce the payoff function of this type of Exotic contract. Using the up-and-in Barrier option type as an example, if the asset price, $S(t)$, remains below the barrier level $B$ throughout the whole option duration, even if at the maturity the asset’s value is higher than the strike price, the option’s payoff would nonetheless be zero. On the contrary, if this threshold was surpassed at any point during this period, the option’s payoff would be similar to that of its European equivalent. The payoff function of this type of option is therefore given by

$$\text{Payoff}_{\text{Barr, call}}(K,T) = \begin{cases} \max(S(T) - K, 0), & \text{if } \exists t < T : S(t) > B \\ 0, & \text{otherwise} \end{cases}$$

$$\text{Payoff}_{\text{Barr, put}}(K,T) = \begin{cases} \max(K - S(T), 0), & \text{if } \exists t < T : S(t) > B \\ 0, & \text{otherwise} \end{cases}$$

Before simulating Barrier options and studying their behavior, we can deduce empirically the effect of the barrier level $B$ on the overall price of the option. For an up-and-in Barrier option, if the barrier level is too high, the price of the option will be very low. This is due to the fact that the likelihood of a stock price increasing enough to surpass such a high barrier level, activating the option, is very low. On the other hand, if the barrier level is very close to $S_0$, the probability of the stock price reaching this threshold is very high. Thus, the price of such an option would be very similar to that of its European equivalent. With these two examples, we can conclude that the higher the barrier level, the lower the Barrier option price.
From eq.(2.2) we can furthermore conclude that the prices of Barrier options are always smaller than or equal to those of their equivalent European counterparts (i.e. with same strike and maturity). This should be straightforward, since the Barrier option becomes equal to its European equivalent only if the Barrier threshold is surpassed and is worthless otherwise.

Though Exotic options are used by banks and investors every day, we will mainly focus on European options: not only are these the most common type of option traded, as we mentioned before, but data is also readily available for many different maturities and strike prices, making European options ideal for model calibration and validation, which will be the main goal of this thesis. Barrier options will nonetheless be implemented and studied, though no data will be used to verify the models’ validity in this case.

2.2 Option Prices and Payoffs

It is important to emphasize the difference between an option’s payoff and its profit for investors. Because options grant the right to buy/sell some asset, no investors would exercise an option if this action was disadvantageous to them (i.e. negative payoff value). Thus, the payoff of an option is always positive (it can also, obviously, be zero). This might sound like an arbitrage possibility (i.e. the chance of making profit without risk, which is very unlikely to occur [Wilmott, 2013]), but in reality, as we mentioned before, options have a price that investors have to pay to acquire them. This means that even if the option’s payoff is positive, if this value is lower than the price an investor paid to buy the option, that investor will actually lose money. The profit of an option is thus the difference between its payoff and its price, which can be negative. With this concept in mind, we can price options by setting their expected profit to be the same as a risk-neutral investment, (e.g. bank deposit). The price of an option can thus be deduced as it’s expected future payoff, discounted back to the present

\[
\text{Price}(K, t^*) = e^{-rT} E[\text{Payoff}(K, t^*)],
\]  

(2.3)

where \(t^*\) denotes the time at which the option is exercised and \(r\) corresponds to the risk-free interest rate, which we will approach in section 2.3. In particular, with eqs.(2.1) in mind, the price functions of European call and put options are clearly given by

\[
C(K, T)_{\text{Euro}} = e^{-rT} E[\max(S(T) - K, 0)] = e^{-rT} E \left[ (S(T) - K) \mathbb{1}_{\{S(T) > K\}} \right];
\]  

(2.4a)

\[
P(K, T)_{\text{Euro}} = e^{-rT} E[\max(K - S(T), 0)] = e^{-rT} E \left[ (K - S(T)) \mathbb{1}_{\{S(T) < K\}} \right],
\]  

(2.4b)

with \(C(K, T)\) and \(P(K, T)\) being the values (i.e. prices) of European call and put options, respectively, and \(E[\cdot], \mathbb{1}_{\{\cdot\}}\) corresponding to the expected value and indicator functions, respectively.

When selling or buying options, investment banks add some premium to this zero-profit price, to account for the risk taken. Though this premium is important to define, it is besides the scope of this work and will not be considered here.
2.2.1 Put-Call Parity

One important aspect of option prices is known as put-call parity. It can be easily shown that the prices of call options are inherently related to the prices of put options with the same strike prices and maturities. This relationship is given by

\[ C(K, T) = S(0) - Ke^{-rT} + P(K, T), \]  

(2.5)

where \( S(0) \) denotes the stock price at inception (i.e. when the option is bought). Because of this duality, we can always easily obtain the prices of put options from the prices of call options with the same underlying asset, maturity and strike. For this reason, some of the results presented in later sections only apply to call options, though we can just as easily find their put option equivalent.

2.3 Black-Scholes Formulae

Due to their high importance, options have been studied in great detail in the past. Probably the most important result in this field came from Fischer Black, Myron Scholes and Robert Merton, who developed a mathematical model to price European options - the famous Black-Scholes (BS) model [Black and Scholes, 1973] - still in use in present days [Wilmott, 2006].

This model states that the price of a European (call or put) option follows the partial differential equation (PDE)

\[ \frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV = 0, \]  

(2.6)

where \( V \) is the price of the option, \( S \) is the price of the underlying (risky) asset, \( r \) is the risk-free interest rate and \( \sigma \) is the stock price volatility. The underlying asset is commonly referred to as stock, so these terms will be used interchangeably in the following sections.

**Proof** Itô’s Lemma can be applied to our option price \( V \), which depends on the (stochastic) stock price \( S \) and time \( t \), so that we obtain

\[ dV = \frac{\partial V}{\partial t} dt + \frac{\partial V}{\partial S} dS + \frac{1}{2} \frac{\partial^2 V}{\partial S^2} (dS)^2. \]  

(2.7)

We now assume that the stock price \( S \) follows a geometric Brownian Motion,

\[ dS(t) = rS(t)dt + \sigma S(t)dW(t), \]  

(2.8)

where \( \{W(t), t > 0\} \) is a Brownian motion process.

It can be shown that \((dW)^2 = dt, (dt)^2 = 0 \) and \((dt)(dW) = 0\). With these properties in mind, we can substitute eq.(2.8) into eq.(2.7), giving

\[ dV = \frac{\partial V}{\partial t} dt + \frac{\partial V}{\partial S} (rSdt + \sigma SdW) + \frac{1}{2} \frac{\partial^2 V}{\partial S^2} (dS)^2 \\ = \left( rS \frac{\partial V}{\partial S} + \frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} \right) dt + \sigma S \frac{\partial V}{\partial S} dW. \]  

(2.9)
We now construct a portfolio where we sell one option and buy an amount $\partial V/\partial S$ of stocks. The value of such a portfolio would be

$$\Pi = -V + \frac{\partial V}{\partial S} S.$$  \hfill (2.10)

From this equation we can easily derive the change of the portfolio’s value, $d\Pi$, in the time interval $dt$ as

$$d\Pi = -dV + \frac{\partial V}{\partial S} dS = \left( \frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} \right) dt.$$

(2.11)

Because the portfolio’s value doesn’t depend on the Brownian motion process $\{W(t), t > 0\}$, it follows that it must be riskless. To avoid any arbitrage possibilities (i.e. making profit without risk, which is very unlikely to happen), the value of this portfolio must be the same as any risk-free asset. The value of a portfolio with such an asset would change with time as

$$d\Pi = r\Pi dt.$$  \hfill (2.12)

Substituting eqs.(2.10) and (2.11) into eq.(2.12) gives

$$\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV = 0.$$  \hfill (2.13)

The risk-free interest rate (or simply interest rate), $r$, is the interest an investor would receive from any risk-free investment (e.g. treasury bills). No investor should ever invest in risky products whose expected return is lower than this interest (e.g. the lottery), since there’s the alternative of obtaining a higher (expected) payoff without the disadvantage of taking risks. In general, this rate changes slightly with time and is unknown. Black et al., in their original model (eq.(2.6)), assumed that this rate is a known function of time. Some authors have suggested solutions to deal with this shortcoming, providing stochastic models to replicate the behavior of interest rates [Heath et al., 1992], but because option prices do not significantly depend on this value [Wilmott, 2006], in the remainder of this thesis we shall set this rate to some constant.

As for the stock price volatility, $\sigma$, since we will explore it to great extent in chapter 3, suffice it to say for now that it is a measure of the future stock price movement’s uncertainty.

Some companies decide to grant their shareholders a part of the profits generated, known as dividends. This action decreases the company’s total assets, which decreases the value of stocks, changing option prices. Because this occurrence is based on human behavior, it is extremely hard to model. Usually, for simplicity, it is assumed to be a constant negative rate, having the exact opposite impact as the risk-free interest rate. Furthermore, Black et al. assumed in their models that no dividends were paid throughout the option’s duration. For both these reasons, we will set dividend payment to zero in all our models.
One other important assumption of the BS model is that stock prices follow a stochastic process, known as Geometric Brownian Motion, defined as

$$dS(t) = rS(t)dt + \sigma S(t)dW(t),$$  \hspace{1cm} (2.14)

with \( \{W(t), t > 0\} \) defining a one-dimensional Brownian motion and where we define \( S_0 = S(0) \) as the stock price at inception (i.e. \( t = 0 \)). An example of such processes is represented in Figure 2.2.

Observing market behavior, we can see that stocks prices seem to behave stochastically. To model them, we should use some diffusion process. Many diffusion processes exist, and choosing the GBM to model stock prices, as done by Black et al., might seem a bit arbitrary, but there is actually a good reason behind it: changes in the stock price are geometric and not arithmetic. If a stock with price 1000€ changed by 9€, we would barely take notice. If another stock with price 10€ changed by 9€, the drop would be quite surprising, even though the change was the same in both assets. This seems to indicate that changes in the stock price depend on the stock price itself and justifies the choice made by Black et al. to model stock prices using a Geometric Brownian Motion process.

![Figure 2.2: Example of three Geometric Brownian Motion processes with maturity \( T = 1\text{yr} \), interest rate \( r = 0.01\text{yr}^{-1} \), volatility \( \sigma = 0.1\text{yr}^{-1/2} \) and initial stock price \( S_0 = 1€ \).](image)

With this result, pricing options is fairly straightforward - we simply need to solve the PDE in eq.(2.6) as we would for the diffusion equation’s initial value problem [Dilão et al., 2009]. The results published originally by Black et al. state that call and put options can be valued as

\[
C(K, T) = N(d_1)S_0 - N(d_2)Ke^{-rT}; \hspace{1cm} (2.15a)
\]
\[
P(K, T) = -N(-d_1)S_0 + N(-d_2)Ke^{-rT}, \hspace{1cm} (2.15b)
\]

where \( N(\cdot) \) is the cumulative distribution function of the standard normal distribution and where \( d_1, d_2 \)
are given by

\[ d_1 = \frac{1}{\sigma \sqrt{T}} \left[ \log \left( \frac{S_0}{K} \right) + \left( r + \frac{\sigma^2}{2} \right) T \right] ; \]

\[ d_2 = d_1 - \sigma \sqrt{T}. \]

(2.16a) (2.16b)

In Figure 2.3 we represent the values of call and put options at both the inception \((t = 0)\) and at maturity \((t = T)\). Notice how at maturity the value functions tend to the payoff functions, shown in Figure 2.1 (take into account that the x-axis in Figure 2.1 represents \(S(T)\) and in Figure 2.3 we have \(K/S_0\), so they are inverted).

Figure 2.3: Call and Put option values at inception and maturity with \(T = 0.5\text{yr}\), interest rate \(r = 0.01\text{yr}^{-1}\), volatility \(\sigma = 0.3\text{yr}^{-1/2}\) and initial stock price \(S_0 = 1\text{€}\).

Eqs.(2.15) are a very important result that can be used to precisely price European options, so long as all the parameters are exactly known and remain constant throughout the option’s duration. Both assumptions are never true for any real market option, though.
Chapter 3

Volatility

As mentioned before, volatility is a measure of the uncertainty of future stock price movements. In other words, a higher volatility will lead to greater future fluctuations in the stock price, whereas a stock with lower volatility is more stable. This phenomenon is exemplified in Figure 3.1, where we can see the greater fluctuations of the high-volatility process (red line) compared to the much smaller variations of the low-volatility process (orange line), using the same driving Brownian motion.

![Figure 3.1: Example of three identical GBM processes with different volatilities. We used a maturity of $T = 1\text{yr}$, an interest rate $r = 0.01\text{yr}^{-1}$ and an initial stock price $S_0 = 1\€$. To emphasize this effect, the underlying Brownian Motion $\{W(t), t > 0\}$ used to generate all three paths was the same.](image)

3.1 Why Volatility is Important

Volatility is of the utmost importance when trading options because it heavily impacts the option price: volatility is very desirable to investors when buying options, which means that the higher the volatility of a stock, the higher the price of its corresponding option. To understand why this occurs, we can
note that high volatility means that there is an increased probability that the stock price will increase or decrease very significantly. In the case of a call option, if the stock price increases considerably, the investor earns a large amount of money. If the price decreases considerably, the investor may let the option expire, thus avoiding further losses. Thus, we see that a higher volatility creates a greater chance of (unlimited) profits with a limited potential downfall. We thus conclude that a higher volatility increases the value of an option. Furthermore, of all the parameters in the BS formula (eq.(2.6)), volatility is the only one we can’t easily measure from market data. Finally, forecasting volatility is even more difficult since this quantity changes with time [S&P Dow Jones Indices]. These three factors make volatility one of the most important subjects in all of mathematical finance and thus the focus of much research.

3.2 Estimating Volatility

Usually, volatility can be estimated empirically from the standard deviation of the historical rate of log-returns [Hull, 2009]. We begin by measuring the stock price at fixed time intervals (e.g. daily, monthly), such that $S_i$ corresponds to the stock price at the end of the $i$th interval. We define the log-return rate, $u_i$, as

$$u_i = \log \left( \frac{S_i}{S_{i-1}} \right).$$  \hspace{1cm} (3.1)

We can then calculate the standard deviation, $s$, of this rate as

$$s = \sqrt{\frac{1}{n-1} \sum_{i=1}^{n} (u_i - \bar{u})^2},$$  \hspace{1cm} (3.2)

assuming we have $n + 1$ observations and denoting $\bar{u}$ as the average value of the log-return rates. The volatility (measured yearly) can be estimated with

$$\hat{\sigma} = \frac{s}{\sqrt{\tau}},$$  \hspace{1cm} (3.3)

where $\tau$ defines the time interval length measured in years. As an example, if we only have monthly data for the $S_i$ prices, the time interval would obviously be one month, which, measured in years is equal to $1/12$, which corresponds to $\tau$. The volatility can also be measured in other time periods: we can define a monthly or a daily volatility, instead of a yearly volatility as we defined before, but these are less common and will therefore not be used.

We are now able to estimate the volatility of any given asset at the present moment. With this result, we could assume that the volatilities remain constant over time and use today's volatility to price options with maturities in the future. The clear problem with this approach is that, when observing market data, we can see that volatilities change over time, so that even if we had the exact value of this parameter in the present, it can, and will, change in the future. If we try to price options assuming a constant volatility, our options will become mispriced, causing potential losses. Our goal is therefore to model the instantaneous volatility (i.e. the volatility at a given point in time) and, with this model, predict its future
behavior, using this knowledge to better price options. We begin by introducing the concept of implied volatility, crucial to fully grasping the concepts used later. Afterwards, we will introduce four models to replicate volatility: one using local volatility (Dupire’s formula), where we assume that the volatility depends on the stock price and time (i.e. \( \sigma = \sigma(t, S(t)) \)), and three others using stochastic volatility (Heston and Static/Dynamic SABR), where the volatility also depends on a Brownian motion process (i.e. \( \sigma = \sigma(t, S(t), W(t)) \)), with the Brownian motion process \( \{W(t), t > 0\} \).

We should note that other very common models exist. The GARCH model [Bollerslev, 1986] (Generalized Autoregressive Conditional Heteroskedasticity) along with all its many variations (EGARCH, NGARCH, ...) is particularly popular among econometricians. However, this model is mostly used to forecast volatility, and performs poorly when used to price derivatives [Chourdakis, 2008]. Because pricing is our objective, GARCH will not be covered in this work. We will also study the constant volatility model, as done by Black et al., and use it as a benchmark for the quality of our models.

### 3.3 Implied Volatility

*Implied volatility* can be defined as the value of stock price volatility that, when input into the BS pricer in eq.(2.15), outputs a value equal to the market price of a given option. In other words, it would be the stock price volatility that the seller/buyer of the option used when pricing it (assuming the BS model was used).

We can also relate the implied volatility to the volatility of the stock price as

\[
\sigma_{imp} = \sqrt{\frac{1}{T} \int_0^T (\sigma(t))^2 dt},
\]

where \( \sigma_{imp} \) denotes the implied volatility and \( \sigma(t) \) is the instantaneous volatility of the stock price. Thus, the implied volatility can be thought of as the (root mean square) average of the instantaneous volatility.

Because eq.(2.15) is not explicitly invertible w.r.t. \( \sigma \), we need to use some numerical procedure (e.g. Newton’s method) to find the value of implied volatility that matches the market price with the model price, i.e. we must find, numerically, the solution to the equation

\[
C(\sigma_{imp}) = C_{mkt},
\]

where \( C(\sigma_{imp}) \) corresponds to the result of eq.(2.15) using \( \sigma_{imp} \) as (implied) volatility and \( C_{mkt} \) corresponds to the price of the call option observed in the market (it could also be the call option price resulting from a model or simulation).

We deduced in section 3.1 that the relation between implied volatility and option price is a monotonous increasing function. This means that we can obtain the implied volatility of an option from its price and vice versa (i.e. the relationship is bijective). This duality is so fundamental that investors often disclose options by providing their implied volatility instead of their price [Wilmott, 2013], as is indeed the case for the data we will use later to calibrate the models.
One important property of implied volatility is that, in the real-world, it depends on the strike price and the maturity. This should not occur in the "Black-Scholes world". Because the volatility is a property of the stock, if investors really used the BS model to price their options, two options with the same underlying stock should have the same implied volatility, regardless of their strike prices or maturities (i.e. the same stock can’t have two different volatilities at the same time). However, when observing real market data, this is in fact what is observed.

The implied volatilities’ dependence on the strike price can take one of two forms, known as smile and skew. An implied volatility smile presents higher volatilities for options with strikes farther from the current stock price (i.e. the shape of a smile). A skew, on the other hand, only presents higher volatilities in one of these directions, either for strikes greater or smaller than the current stock price (i.e. the shape of a skew). Both phenomena are represented in Figure 3.2.

Because of their higher implied volatility, we can conclude that, if we observe a smile in the data, options with strikes different from the current stock price are overpriced. The reason behind this odd market behavior is related to the simple demand-supply rule [Wilmott, 2006]. On the one hand, some investors are risk-averse and want to hedge their losses in case of a big market movement (as explained in subsection 1.3.1). They don’t mind paying a higher price for an option if this means they would be relatively safe from potentially devastating price changes. For this reason, the demand of call options with lower strikes increases, driving their prices and, consequently, their implied volatilities up. On the other hand, other investors are risk-seekers and want to take advantage of possible sudden price movements, buying the stocks after the possible price increase for the lower strike prices. They don’t mind paying higher prices for the chance of earning high profits and this drives the prices of high strike call options and, consequently, their implied volatility up. This fear-greed duality gives rise to the observed volatility smile. In the case of the volatility skew, only one of the two phenomena described occurs.

The presence of a smile in the data instead of a skew, and vice-versa, is determined by the type of product serving as underlying asset - Forex market options usually exhibit volatility smiles whereas index and commodities options usually show a volatility skew or a skewed smile [Wilmott, 2006].
The dependence of the implied volatility on the maturity date is more complex, but in general it decreases with the maturity.

In Figure 3.3 we plot an example of an implied volatility surface, along with its contour plot, which we obtained from real market data. This surface is again represented in section 5.2.

![Implied Volatility Surface and Contour Plot](image)

Figure 3.3: Representation of an implied volatility surface and its respective contour plot.

As we can see from Figure 3.3 in this case we have a mixture of a smile and a skew behavior and the implied volatility does decrease with maturity, as expected.

It can also be shown that the implied volatility is the same for calls and puts [Hull, 2009], though the causes of the volatility smile/skew for put options are the opposite of the ones described before for calls.

### 3.4 Option Price Sensitivity and Vega

When studying volatilities, as is our case, one of the most important aspects to consider is the sensitivity of the option price to the volatility. In other words, we should try to understand how a small variation in the volatility of a given option affects its price. This sensitivity can be considered for other parameters, such as the interest rate or the maturity, but it is particularly important for the volatility because we don’t actually know the exact value of this parameter. Therefore, if the option price is very sensitive to the volatility and we have a bad estimation for this parameter, we will have severe mispricing problems and possibly lose high amounts of money.

This sensitivity has been deeply studied in the literature and is usually called Vega, or $\nu$. It is defined as

$$\nu = \frac{\partial V}{\partial \sigma}, \hspace{2cm} (3.6)$$

where $V$ denotes the option price. In particular for European calls, this value can be shown to be [Hull, 2009]

$$\nu = S_0 \sqrt{T} N'(d_1), \hspace{2cm} (3.7)$$
where $d_1$ is given in eq.(2.16) and $N'(\cdot)$ is the probability density function for a standard normal distribution. If we plot this quantity against option strikes, we obtain the curve shown in Figure 3.4.

As we can see, the Vega peaks when the strike equals the option price. This means that, at such strikes, a variation in the volatility will produce the largest variation on the corresponding strike price. Furthermore, we can see that this peak is more pronounced for later maturities.

Despite its usefulness, the Vega doesn’t quite grasp the whole picture. As we said before, prices behave geometrically and not arithmetically - a change of 0.01 € in an option with price 0.5 € is quite different from the same change in an option with price 0.02 €. A derivative (such as Vega) assumes arithmetic variations i.e. $\partial A / \partial B = 0.1$ means that a change of 0.1 in $B$ produces a change of 1 in $A$. This doesn’t contain any information on the relative change of $A$ (i.e. if $A$ was an option price, we wouldn’t know if it changed by 10% or 0.1%). To solve this shortcoming, we can simply define the relative change as

$$\text{Relative Change} = \frac{\partial V}{\partial \sigma} \frac{\sigma}{V},$$

which we plot in Figure 3.5, for call options, against their strike price. As an example, if we have a relative change of 5, this means that a variation of 1% in the volatility will produce a variation of 5% in the option price. This relationship is represented in Figure 3.5.
As we can see in Figure 3.5, the relative change of the option price w.r.t. volatility is very large for call options with high strikes. We can therefore conclude that the prices of options with high strikes are very sensitive to the value of volatility. This implies that a very slight (relative) change in the volatility will produce a very large (relative) change in the option price. It also means that the volatility is very robust w.r.t. the option price, i.e. a very large (relative) variation in the option price will barely affect the volatility. We will observe this effect in later sections.

The opposite effect is found for call options with lower strikes - we can see that the relative variation of the option price w.r.t. the volatility is extremely small in these cases, meaning that the option price is extremely robust to the volatility, i.e. a change in the volatility will affect the option price only very slightly. It also implies that the volatility is extremely sensitive to the option price, meaning that a very slight (relative) change in the price of a call option with low strikes will dramatically change its volatility. This observation will become very important in later sections.

Furthermore, we can also observe that the relative change of the option price w.r.t. the volatility is greater for options with smaller maturities, which will also become important later.

For future reference, the value of relative change of the option price w.r.t. the volatility is approximately 1 when $K = S_0$ for all maturities.
3.5 Local Volatility

In their original work, Black et al. assumed that volatility is constant throughout the whole option duration [Black and Scholes, 1973]. From market data, it can be clearly seen that this is not the case [S&P Dow Jones Indices]. There may be times when new information reaches the market (e.g. the results of an election) and trading increases, driving volatility up. It is equally true that shortly before this information is known, trading may stall due to expectancy, and volatilities go down.

The constant volatility BS model is therefore clearly insufficient to completely grasp real-world trading. We should use a model where volatility is dynamic, measuring the uncertainty on the stock price movement at any point in time. However, as we saw in section 3.3, the market's view of volatility also depends on the stock price itself. The volatility should therefore be a function of both time and stock price: \( \sigma(S(t), t) \). We call this model local volatility and the geometric Brownian motion from eq.(2.14) is transformed into the new diffusion process

\[
dS(t) = rS(t)dt + \sigma(S(t), t)S(t)dW(t),
\]

where \( \sigma(S(t), t) \) is a function of \( S(t) \) and \( t \), with certain properties, which we omit as they are only used to ensure the strong solution of this SDE (i.e. \( \sigma(S(t), t) \) is "well behaved").

This local volatility model implies that we have a nonlinear deterministic volatility surface, \( \sigma(S(t), t) \), which can be thought of as the market's expectation of future volatility at time \( t \) if the stock price is \( S(t) \) at that time.

Because we can't directly measure the local volatility of a stock from market data, we need some models to estimate it. One of the most used of these is known as Dupire's formula, which we explain next.

3.5.1 Dupire’s model

One of the most famous results in the modelling of the local volatility function was obtained by Dupire [Dupire, 1994]. In his article, this author derives a theoretical formula for \( \sigma(S(t), t) \), given by

\[
\sigma(S(t), t) = \sqrt{\frac{\partial C}{\partial T} + rS \frac{\partial C}{\partial K} \frac{1}{2} S^2 \frac{\partial^2 C}{\partial K^2}},
\]

where \( C = C(K, T) \) is the price of a European call option with strike price \( K \) and maturity \( T \). All the derivatives are evaluated at \( K = S(t) \) and \( T = t \).

**Proof**

We begin by assuming that the stock price \( S(t) \) follows a dynamic transition probability density function \( p(S(t), t, S'(t'), t') \). In other words, by integrating this density function we would obtain the probability of the stock price reaching a price \( S' \) at a time \( t' \) having started at price \( S \) at time \( t \).

The present value of a call option, \( C(K, T) \), can be deduced as its expected future payoff, discounted
backwards in time, which results in
\[
C(K, T) = e^{-r(T-t)}\mathbb{E}\left[\max(S' - K, 0)\right] = e^{-r(T-t)} \int_0^\infty \max(S' - K, 0) p(S, t, S', T) dS' \\
= e^{-r(T-t)} \int_K^\infty (S' - K) p(S, t, S', T) dS',
\]
(3.11)
where \(S'\) denotes the stock price at maturity.

Taking the first derivative of this result with respect to the strike price \(K\), we obtain
\[
\frac{\partial C}{\partial K} = -e^{-r(T-t)} \int_K^\infty p(S, t, S', T) dS'.
\]
(3.12)
The second derivative results in
\[
\frac{\partial^2 C}{\partial K^2} = e^{-r(T-t)} p(S, t, K, T),
\]
(3.13)
assuming \(p(S, t, \infty, T) = 0\).

We now make a brief digression to derive the Fokker-Planck equation (following the procedure shown in Wilmott [Wilmott, 2006]), which we require for the next steps. This equation is widely used in stochastic calculus and is applicable to stochastic processes in general. To make its proof simpler, we make a simplification assuming that the stochastic process is a stock price following a trinomial model: at each time step \(\delta t\), the stock price can only increase or decrease by an amount \(\delta S\), with probabilities \(\phi^+(S, t)\) and \(\phi^-(S, t)\), respectively, or remain the same, with probability \((1 - \phi^+(S, t) - \phi^-(S, t))\). The resulting equation still works, however, for any general stochastic process.

Assuming the trinomial model, the expected value of the change is given by
\[
\phi^+ \delta S + (1 - \phi^+ - \phi^-)0 + \phi^- (-\delta S) = (\phi^+ - \phi^-)\delta S,
\]
(3.14)
and its variance is approximately given by
\[
(\delta S)^2(\phi^+ + \phi^- - (\phi^+ - \phi^-)^2) \approx (\phi^+ + \phi^-)(\delta S)^2
\]
(3.15)
where we take only the first order terms. The expected value of the change of a Geometric Brownian Motion can be thought of as its drift term (i.e. \(rS\delta t\)), and the variance is its stochastic term squared (i.e. \((\sigma SdW)^2 = \sigma^2 S^2 \delta t\)), so that we have
\[
rS\delta t = (\phi^+ - \phi^-)\delta S;
\]
(3.16a)
\[
\sigma^2 S^2 \delta t = (\phi^+ + \phi^-)(\delta S)^2,
\]
(3.16b)
from which we can derive the probabilities \(\phi^+\) and \(\phi^-\) as
\[
\phi^+(S, t) = \frac{1}{2} \frac{\delta t}{\delta S^2} (rS\delta S + \sigma^2 S^2);
\]
(3.17a)
\[
\phi^-(S, t) = \frac{1}{2} \frac{\delta t}{\delta S^2} (-rS\delta S + \sigma^2 S^2).
\]
(3.17b)
We can now move backwards and derive the probability of reaching the price $S'$ at time $t'$ having started at the previous time $t' - \delta t$ with some (unknown) price $S$, which could be either $S' + \delta S$, $S' - \delta S$ or $S'$ (assuming a trinomial movement). Applying the same logic as before, the probability of reaching $S'$ at time $t'$, having started at $S$ at time $t$, is the same as the probability of being at $S' - \delta S$ at time $t' - \delta t$ and moving up, plus the probability of being at $S' + \delta S$ at time $t' - \delta t$ and moving down plus the probability of being at $S'$ at time $t' - \delta t$ and remaining at the same value, since these three cases cover all possible paths leading to $S'$ at time $t'$. We can thus derive the transition probability density, $p(S,t,S',t')$ as

$$p(S,t,S',t') = \phi^-(S' + \delta S, t' - \delta t) p(S,t,S' + \delta S, t' - \delta t)$$

$$+ (1 - \phi^+(S', t' - \delta t) - \phi^-(S', t' - \delta t)) p(S,t,S', t' - \delta t)$$

$$+ \phi^+(S' - \delta S, t' - \delta t) p(S,t,S' - \delta S, t' - \delta t)$$

(3.18)

If we expand each term on its Taylor series around point $(S', t')$, we get

$$p(S,t,S',t') = \phi^-(S' + \delta S, t' - \delta t) \left( p(S,t,S', t') + \delta S \frac{\partial p}{\partial S} + \frac{1}{2} (\delta S)^2 \frac{\partial^2 p}{\partial S^2} - \delta t \frac{\partial p}{\partial t} \right)$$

$$+ (1 - \phi^+(S', t' - \delta t) - \phi^-(S', t' - \delta t)) \left( p(S,t,S', t') - \delta t \frac{\partial p}{\partial t} \right)$$

$$+ \phi^+(S' - \delta S, t' - \delta t) \left( p(S,t,S', t') - \delta S \frac{\partial p}{\partial S} + \frac{1}{2} (\delta S)^2 \frac{\partial^2 p}{\partial S^2} - \delta t \frac{\partial p}{\partial t} \right).$$

(3.19)

from which, collecting all the terms, we can derive the famous Fokker-Planck equation [Wilmott, 2006] (with rather sloppy notation) as

$$\frac{\partial p}{\partial t} = \frac{1}{2} \frac{\partial^2 (\sigma^2 S'^2 p)}{\partial S'^2} - \frac{\partial (r S' p)}{\partial S'}.$$

(3.20)

where we have used $t' = T$.

From eq.(3.11) we can easily obtain the first derivative w.r.t. time

$$\frac{\partial C}{\partial T} = -rC + e^{-r(T-t)} \int_K^{\infty} (S' - K) \frac{\partial p}{\partial T} dS',$$

(3.21)

where, for simplicity, we drop the terms of the transition probability density, $p$.

Using the Fokker-Planck formula in eq.(3.20), we can transform this relation into

$$\frac{\partial C}{\partial T} = -rC + e^{-r(T-t)} \int_K^{\infty} (S' - K) \left( \frac{1}{2} \frac{\partial^2 (\sigma^2 S'^2 p)}{\partial S'^2} - r \frac{\partial (S' p)}{\partial S'} \right) dS'.$$

(3.22)

We now split the terms in the integral to evaluate them independently. We integrate the second term by parts as

$$\int_K^{\infty} (S' - K) \left( -r \frac{\partial (S' p)}{\partial S'} \right) dS' = -r(S' - K) (S' p)|_{S' = K} + r \int_K^{\infty} S' p dS'$$

$$= r \int_K^{\infty} (S' - K) p dS' + r K \int_K^{\infty} p dS'$$

$$= e^{(T-t)} r K \frac{\partial C}{\partial K}.$$
where in the first step we assumed that \( p \) and its first derivative w.r.t. \( S \) go sufficiently fast to zero when \( S \) goes to infinity and where in last step we used eqs.(3.11) and (3.12).

Turning now to the first term of the integral, we integrate twice by parts as

\[
\int_{K}^{\infty} (S' - K) \left( \frac{1}{2} \frac{\partial^2 (\sigma^2 S^2 p)}{\partial S^2} \right) dS' = \frac{1}{2} (S' - K) \frac{\partial (\sigma^2 S^2 p)}{\partial S'} \bigg|_{S'=K} - \frac{1}{2} \int_{K}^{\infty} \left( \frac{\partial (\sigma^2 S^2 p)}{\partial S'} \right) dS'
\]

\[
= -\frac{1}{2} \sigma^2 S^2 p \bigg|_{S'=K}^{\infty} = \frac{1}{2} \sigma^2 (K, T) K^2 p(S, t, K, T)
\]

where in the last step we used eq.(3.13) and again assumed that \( p \) goes to zero sufficiently fast.

Collecting all the terms, we obtain

\[
\frac{\partial C}{\partial T} = \frac{1}{2} \sigma^2 (K, T) K^2 \frac{\partial^2 C}{\partial K^2} - r K \frac{\partial C}{\partial K}.
\]

(3.25)

from which, by rearranging all the terms and applying the variable change \( \sigma(K, T) \mapsto \sigma(S, t) \), we get

\[
\sigma(S(t), t) = \sqrt{\frac{\frac{\partial C}{\partial T} + r S \frac{\partial C}{\partial K}}{\frac{1}{2} S^2 \frac{\partial^2 C}{\partial K^2}}}
\]

(3.26)

assuming all the derivatives are evaluated at \( K = S(t) \) and \( T = t \).

As can be seen, we need to differentiate the option prices with respect to their strikes and maturities. To achieve this, we need first to gather, from the market, a large number of prices for options with different maturities and strikes. We then implement some interpolation on these values to obtain an option price surface (with \( K \) and \( T \) as variables). Finally, we calculate the gradients of this interpolated surface and input them into eq.(3.10) to obtain the local volatility surface. We can then sample from this surface to obtain the local volatility for any stock price \( S(t) \) at any time \( t \).

A major problem can be pointed out in eq.(3.10). For options far in or far out of the money (i.e. with strikes much greater or much smaller than \( S_0 \)), it can be shown that the option price depends almost linearly on the strike. This means that the second derivative of the price w.r.t. the strike is extremely small in these regions. Because this value is in the denominator of eq.(3.10), the local volatility will explode in such cases, which is unrealistic.

One possible solution to this problem is to relate our local volatility with the implied volatility surface instead of the option price's [Wilmott, 2013]. The relation obtained is

\[
\sigma(S(t), t) = \sqrt{\frac{\sigma^2 \text{imp} + 2t \sigma^2 \text{imp} \frac{\partial \sigma^2 \text{imp}}{\partial T} + 2r(S(t)) t \sigma^2 \text{imp} \frac{\partial \sigma^2 \text{imp}}{\partial K}}{\left(1 + (S(t)) d_1 \sqrt{t} \frac{\partial \sigma^2 \text{imp}}{\partial K} + (S(t))^2 t \sigma^2 \text{imp} \left( \frac{\partial^2 \sigma^2 \text{imp}}{\partial K^2} - d_1 \left( \frac{\partial \sigma^2 \text{imp}}{\partial K} \right)^2 \sqrt{t} \right) \right)^2}},
\]

(3.27)
where $d_1$ is given by

$$
d_1 = \frac{\log(S_0/S(t)) + (r + \frac{1}{2} \sigma_{imp}^2) t}{\sigma_{imp} \sqrt{t}},
$$

with $S_0$ being the stock price at $t = 0$. We define $\sigma_{imp} = \sigma_{imp}(K, T)$ as the implied volatilities of options with maturity $T$, and strike $K$. Furthermore, $\sigma_{imp}$ and all its derivatives are evaluated at $K = S(t)$ and $T = t$. This formula can be obtained from eq.(3.10) by applying the transformation from call prices to implied volatilities.

We now need to generate the implied volatility surface to obtain the gradients needed in eq.(3.27) to generate the local volatility. Again, this surface can be obtained by interpolating between market data for several implied volatilities. The problem with this approach is that we only have access to market data for a very limited set of implied volatilities. This model is therefore very much ill-posed (i.e. a small change in the input generates a very different output) and the resulting local volatility surface might look unrealistic [Wilmott, 2013]. Furthermore, this procedure is heavily dependent on the interpolation/extrapolation method chosen, which is problematic.

As an advantage, we note that because we are directly using the market data, the implied volatility surface is nonparametric and therefore no fitting procedure is required. To ease the problem of ill-posedness, we could heuristically choose some functions to model this surface, fitting their parameters to better replicate the market data, and finally replacing these functions in eq.(3.27), as done by Dewynne [Dewynne et al., 1998]. However, this approach depends heavily on the functions chosen (heuristically) and will not be considered.

Three other problems can be identified in Dupire’s local volatility model. First, it can be shown that the local volatility surface changes with time [Wilmott, 2013]. This means that the whole interpolation procedure must be done regularly for the model to work properly. Secondly, some authors have pointed out that the volatility smile obtained from Dupire’s local-volatility model doesn’t follow real market dynamics [Hagan et al., 2002]: it can be shown that when the price of the stock either increases or decreases, the volatility smile predicted by Dupire’s model shifts in the opposite direction. The minimum of the volatility smile would therefore be offset and no longer correspond to the local stock price (i.e. the spot price). The volatility smile dynamics obtained from the local-volatility model would thus be actually worse than if we assumed a constant volatility model, where the surface doesn’t shift at all. Finally, the gradients used in eq.(3.27) have to be generated numerically. This numerical differentiation is very unstable, especially when done on our rough interpolated surface, which will lead to errors in the local volatility obtained.

As an example, in Figure 3.6 we show a local volatility surface, obtained by applying Dupire’s formula to real data, along with its corresponding contour plot. This surface will again be represented in section 5.2 and studied with greater detail there.

Despite its problems, Dupire’s formula is still very much used by practitioners and performs surprisingly well, as we will see in chapter 5.
3.6 Stochastic Volatility

As stated before, the volatility is not constant, is not observable and is very unpredictable, despite our attempts to model it. This seems to indicate that volatility is itself also a stochastic process [Rebonato, 2004]. Some research has been done into this hypothesis, and many models have been developed to replicate real-world volatilities with this assumption.

We assume that the stock price follows the diffusion process

\[ dS(t) = rS(t)dt + \sigma(S(t), t)S(t)dW_1(t), \]  

(3.29)

and we further hypothesize that the volatility follows

\[ d\sigma(S(t), t) = \rho(S(t), \sigma(S(t), t), t)dt + q(S(t), \sigma(S(t), t), t)dW_2(t), \]  

(3.30)

where \( \rho(S(t), \sigma(S(t), t), t) \) and \( q(S(t), \sigma(S(t), t), t) \) are functions of the stock price \( S(t) \), time \( t \) and of the volatility \( \sigma(S(t), t) \) itself.

We also assume that \( W_1 \) and \( W_2 \) are two Brownian motion processes with a correlation \( \rho(t) \), i.e.

\[ dW_1(t)dW_2(t) = \rho(t)dt, \quad \forall t > 0, \]  

(3.31)

which is usually assumed constant, i.e. \( \rho(t) = \rho \). This correlation coefficient can be explained by the relationship between prices and volatilities [Chourdakis, 2008]. Historically, we can see that high volatility periods usually occur when the market is under stress due to low returns (i.e. stock prices decrease). On the other hand, whenever the market stabilizes and returns increase, the volatility goes down. These factors seem to indicate the existence of a negative correlation between stock prices and volatilities. Thus, to fully grasp market behavior, this correlation must be taken into account.
Choosing the appropriate functions \(p(S(t), \sigma(S(t), t), t)\) and \(q(S(t), \sigma(S(t), t), t)\) is very important since the whole evolution of the volatility and, consequently, also the stock price depends on them. All stochastic volatility models present a different version of these functions, and each may be more adequate for some types of assets. Furthermore, these functions have some parameters that we have to calibrate to best fit our model to market data, as we will see later.

Many stochastic volatility models exist, such as Hull-White [Hull and White, 1987] and Stein-Stein [Stein and Stein, 1991]. However, the Heston model is by far the most popular of these [Chourdakis, 2008]. Another model, known as SABR, is also widely used by practitioners, especially in the interest rate derivative markets (i.e. derivatives whose underlying asset is an interest rate). For these reasons, both models will be studied in this work.

### 3.6.1 Heston Model

The Heston model was developed in 1993 by Steven Heston [Heston, 1993] and it states that stock prices satisfy the relations

\[
\begin{align*}
    dS(t) &= rS(t)dt + \sqrt{\nu(t)}S(t)dW_1(t), \\
    d\nu(t) &= \kappa(\nu(t) - \nu_0(t))dt + \eta\sqrt{\nu(t)}dW_2(t),
\end{align*}
\]

with \(\nu(t)\) corresponding to the stock price variance (i.e. the square of the volatility, \(\nu(t) = (\sigma(t))^2\)) and where \(W_1(t)\) and \(W_2(t)\) have a constant correlation \(\rho\). We furthermore define \(\nu_0\) as the initial variance (i.e. variance at time \(t = 0\)). The original model used a drift parameter \(\mu\) instead of the risk-free measure drift \(r\) presented here, but a measure transformation, using Girsanov’s theorem, can be easily implemented [Rouah, 2013].

The parameters \(\kappa, \bar{\nu}\) and \(\eta\) are, respectively, the mean-reversion rate (i.e. how fast the variance converges to its mean value), the long-term variance (i.e. the mean value of variance) and the volatility of the variance (i.e. how erratic is the variance process).

One of the reasons why the Heston model is so popular is the fact that there exists a closed-form solution for the prices of European options priced under this model. This closed form solution is given by

\[
C_H(K, T; \theta) = e^{-rT}E \left[ (S(T) - K) \mathbb{1}_{\{S(T) > K\}} \mid \theta \right] = e^{-rT} \left( E \left[ S(T) \mathbb{1}_{\{S(T) > K\}} \mid \theta \right] - K E \left[ \mathbb{1}_{\{S(T) > K\}} \mid \theta \right] \right)
\]

\[
= S_0 P_1(K, T; \theta) - e^{-rT}K P_0(K, T; \theta),
\]

where \(C_H(K, T; \theta)\) corresponds to the theoretical European call option price, with strike \(K\) and maturity \(T\), under the Heston model, assuming a parameter set \(\theta = \{\kappa, \bar{\nu}, \eta, \nu_0, \rho\}\). The variables \(P_1(K, T; \theta)\) and \(P_2(K, T; \theta)\) are given by

\[
P_1(K, T; \theta) = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \text{Re} \left( \frac{e^{-iu \log K}}{iu S_0 e^{rT}} \phi(u - i, T; \theta) \right) du,
\]

\[
P_2(K, T; \theta) = \frac{1}{2} - \frac{1}{\pi} \int_0^\infty \text{Im} \left( \frac{e^{-iu \log K}}{iu S_0 e^{rT}} \phi(u - i, T; \theta) \right) du,
\]

\[
P_0(K, T; \theta) = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \text{Re} \left( \frac{e^{-iu \log K}}{iu S_0 e^{rT}} \phi(u - i, T; \theta) \right) du,
\]

\[
P_3(K, T; \theta) = \frac{1}{2} - \frac{1}{\pi} \int_0^\infty \text{Im} \left( \frac{e^{-iu \log K}}{iu S_0 e^{rT}} \phi(u - i, T; \theta) \right) du,
\]

\[
P_4(K, T; \theta) = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \text{Re} \left( \frac{e^{-iu \log K}}{iu S_0 e^{rT}} \phi(u - i, T; \theta) \right) du,
\]

\[
P_5(K, T; \theta) = \frac{1}{2} - \frac{1}{\pi} \int_0^\infty \text{Im} \left( \frac{e^{-iu \log K}}{iu S_0 e^{rT}} \phi(u - i, T; \theta) \right) du.
\]
\[ P_0(K, T; \theta) = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \text{Re} \left( \frac{e^{-iu \log K}}{iu} \phi(u, T; \theta) \right) du, \]  

(3.35)

where \( i \) is the imaginary unit and \( \phi(u, t; \theta) \) is the characteristic function of the logarithm of the stock price process (the characteristic function of a random variable is the Fourier transform of its probability density function).

It is crucial to define the appropriate characteristic function \( \phi(u, t; \theta) \) to evaluate the integrals in eqs.(3.34) and (3.35) and, with them, find the option price with eq.(3.33). In his original article, Heston proposed a solution to this very characteristic function [Heston, 1993]. However, some posterior authors demonstrated that, for large maturities, some discontinuities appeared for the proposed solution [Kahl and Jäckel, 2005]. One possible alternative, proposed by Schoutens [Schoutens et al., 2004], avoids this shortcoming and is given by

\[ \phi(u, t; \theta) = \exp \left\{ iu (\log S_0 + rt) + \frac{\kappa \eta}{\eta^2} \left[ \xi - \alpha \right] t - 2 \log \left( \frac{1 - ge^{-\alpha t}}{1 - g} \right) \right\} + \frac{\nu_0}{\eta^2} \left( \xi - \alpha \right) \frac{1 - e^{-\alpha t}}{1 - ge^{-\alpha t}}, \]  

(3.36)

where we define

\[ \xi = \kappa - \eta \rho iu, \]  

(3.37)

\[ \alpha = \sqrt{\xi^2 + \eta^2 (u^2 + iu)}, \]  

(3.38)

\[ g = \frac{\xi - \alpha}{\xi + \alpha}. \]  

(3.39)

**Proof** We will follow the derivation presented in Gatheral [Gatheral, 2006] with slight changes of variables, for consistency.

We begin by defining Itô’s Lemma for a function \( V \) (such as the price of an option) dependent on the behavior of two diffusion processes \( X \) and \( Y \) (such as the stock price and variance processes, but also applicable to two different stock price processes), which is given by

\[ dV = \frac{\partial V}{\partial t} dt + \frac{\partial V}{\partial X} dX + \frac{\partial V}{\partial Y} dY + \frac{1}{2} \sigma_X^2 \frac{\partial^2 V}{\partial X^2} dt + \rho \sigma_X \sigma_Y \frac{\partial^2 V}{\partial X \partial Y} dt + \frac{1}{2} \sigma_Y^2 \frac{\partial^2 V}{\partial Y^2} dt, \]  

(3.40)

where we have assumed that the two diffusion processes are defined as

\[ dX = \mu_X(X, Y, t) dt + \sigma_X(X, Y, t) dW_X; \]  

\[ dY = \mu_Y(X, Y, t) dt + \sigma_Y(X, Y, t) dW_Y, \]  

(3.41)

where \( W_X \) and \( W_Y \) have a correlation of \( \rho \).

If we apply this lemma (as well as the usual non-arbitrage arguments) to the price of a call option’s value, assuming the diffusion processes to be the stock price and variance defined in eqs.(3.32a) and (3.32b), we arrive at

\[ \frac{\partial C}{\partial t} + \frac{1}{2} \nu S^2 \frac{\partial^2 C}{\partial S^2} + \rho \nu S \frac{\partial^2 C}{\partial v \partial S} + \frac{1}{2} \eta^2 \nu \frac{\partial^2 C}{\partial v^2} + rS \frac{\partial C}{\partial S} - rC + \kappa (v - \nu) \frac{\partial C}{\partial v} = 0. \]  

(3.42)

We now define the forward price as \( F(t) = S(t)e^{r(T-t)} \), and introduce the variables \( \tau = T - t \) and
\[ x(t) = \log \left( \frac{F(t)}{K} \right). \] We furthermore denote \( C^* \) as the future value to expiration of the option price (i.e. \( C^* = C e^T \)). The relation in eq.(3.42) reduces to

\[
- \frac{\partial C^*}{\partial \tau} + \frac{1}{2} \nu \frac{\partial^2 C^*}{\partial x^2} + \rho \eta \nu \frac{\partial^2 C^*}{\partial x \partial \nu} + \frac{1}{2} \eta^2 \nu \frac{\partial C^*}{\partial \nu^2} - \frac{1}{2} \nu \frac{\partial C^*}{\partial x} + \kappa (\nu - \nu) \frac{\partial C^*}{\partial \nu} = 0, \quad (3.43)
\]

which has a solution of the form [Duffie et al., 2000]

\[
C^*(x, \nu, \tau) = Ce^{\tau T} = (S_0 P_1 - e^{-\tau T} K P_0) e^{\tau T} = K [e^x P_1(x, \nu, \tau) - P_0(x, \nu, \tau)]. \quad (3.44)
\]

Substituting the solution of eq.(3.44) in eq.(3.43) implies that \( P_0 \) and \( P_1 \) must satisfy

\[
- \frac{\partial P_j}{\partial \tau} + \frac{1}{2} \nu \frac{\partial^2 P_j}{\partial x^2} - \left( \frac{1}{2} - j \right) \nu \frac{\partial P_j}{\partial x} + \frac{1}{2} \eta^2 \nu \frac{\partial^2 P_j}{\partial x \partial \nu} + (\kappa (\nu - \nu) + j \nu \rho \eta) \frac{\partial P_j}{\partial \nu} = 0, \quad (3.45)
\]

for \( j = 0, 1 \) and subject to the terminal condition \( P_j(x, \nu, \tau = 0) = \mathbb{1}_{\{x > 0\}} \).

To solve this problem, we use a Fourier transform technique. Defining \( \tilde{P}_j \) as the Fourier transform of \( P_j \),

\[
\tilde{P}_j(u, \nu, \tau) = \int_{-\infty}^{\infty} e^{-iux} P_j(x, \nu, \tau) dx, \quad (3.46)
\]

and substituting this result in eq.(3.45) produces

\[
\nu \left\{ \omega_j \tilde{P}_j - \beta_j \frac{\partial \tilde{P}_j}{\partial \nu} + \frac{\eta^2}{2} \frac{\partial^2 \tilde{P}_j}{\partial \nu^2} \right\} + \kappa \eta \nu \frac{\partial \tilde{P}_j}{\partial \nu} - \frac{\partial \tilde{P}_j}{\partial \tau} = 0, \quad (3.47)
\]

with

\[
\omega_j = -\frac{u^2}{2} - \frac{iu}{2} + iju, \quad (3.48)
\]

\[
\beta_j = \kappa - \rho \eta u - \rho \eta j. \quad (3.49)
\]

Heston proposed that \( \tilde{P}_j \) is a function of the form

\[
\tilde{P}_j(u, \nu, \tau) = \frac{1}{iu} \exp \{ \zeta_j(u, \tau) \nu + \psi_j(u, \tau) \nu \}. \quad (3.50)
\]

We can therefore derive

\[
\frac{\partial \tilde{P}_j}{\partial \tau} = \left\{ \nu \frac{\partial \zeta_j}{\partial \tau} + \nu \frac{\partial \psi_j}{\partial \tau} \right\} \tilde{P}_j, \quad (3.51)
\]

\[
\frac{\partial \tilde{P}_j}{\partial \nu} = \psi_j \tilde{P}_j, \quad (3.52)
\]

\[
\frac{\partial^2 \tilde{P}_j}{\partial \nu^2} = \psi_j^2 \tilde{P}_j. \quad (3.53)
\]

Thus, eq.(3.47) is only satisfied if

\[
\frac{\partial \zeta_j}{\partial \tau} = \kappa \psi_j, \quad (3.54)
\]

\[
\frac{\partial \psi_j}{\partial \tau} = \omega_j - \beta_j \psi_j + \frac{\eta^2}{2} \psi_j^2. \quad (3.55)
\]
Integrating these solutions with terminal conditions $\zeta_j(u, 0) = \psi_j(u, 0) = 0$, yields

$$\zeta_j(u, \tau) = \frac{\kappa}{\eta^2} \left[ (\beta_j - \gamma_j) \tau - 2 \log \left( \frac{1 - g_j e^{-\gamma_j \tau}}{1 - g_j} \right) \right], \quad (3.56)$$

$$\psi_j(u, \tau) = \frac{1}{\eta^2} (\beta_j - \gamma_j) \frac{1 - e^{-\gamma_j \tau}}{1 - g_j e^{-\gamma_j \tau}}, \quad (3.57)$$

where we define

$$\gamma_j = \sqrt{\beta_j - 2 \omega_j \eta^2}, \quad (3.58)$$

$$g_j = \frac{\beta_j - \gamma_j}{\beta_j + \gamma_j}. \quad (3.59)$$

We finally arrive at the solution for $P_j$ given by

$$P_j(x, \nu, \tau) = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \Re \left( \frac{\exp \left\{ \zeta_j(u, \tau) \nu + \psi_j(u, \tau) \nu + iux \right\}}{iu} \right) du. \quad (3.60)$$

A change of variables is possible, as shown by Crisostomo [Crisóstomo, 2015], such that the two different characteristic functions for $P_1$ and $P_0$ can be transformed into a single one by defining

$$P_1 = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \Re \left( \frac{e^{-iu \log K_{iu} S_0 e^{rt \phi(u, T; \theta)}}}{iu} \right) du, \quad (3.61)$$

$$P_0 = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \Re \left( \frac{e^{-iu \log K_{iu} S_0 e^{rt \phi(u, T; \theta)}}}{iu} \right) du, \quad (3.62)$$

with the characteristic function $\phi(u, T; \theta)$ given by

$$\phi(u, T; \theta) = \exp \left\{ iu \log S_0 + rt \right\} + \frac{\kappa \nu}{\eta^2} \left[ (\xi - \alpha) t - 2 \log \left( \frac{1 - ge^{-\alpha t}}{1 - g} \right) \right] + \frac{\nu_0}{\eta^2} (\xi - \alpha) \frac{1 - e^{-\alpha t}}{1 - ge^{-\alpha t}}. \quad (3.63)$$

The main problem with the characteristic function presented in eq.(3.36) is the fact that it is highly nonlinear. Because we will apply some optimization procedure to minimize the difference between the model and the market option prices (i.e. calibration), the optimizer is very likely become stuck in some local minimum and not find the globally optimal solution. This shortcoming led some authors to propose several modified versions of this function, such as Rollin et al. [del Baño Rollin et al., 2010]. Most recently, Cui et al. [Cui et al., 2017] presented a characteristic function that not only doesn’t have the previously mentioned discontinuities but also solves the nonlinearity problem, given by

$$\phi(u, t; \theta) = \exp \left\{ iu \log S_0 + rt \right\} + \frac{\kappa \nu}{\eta^2} \left[ (\xi - \alpha) t - 2 \log \left( \frac{1 - ge^{-\alpha t}}{1 - g} \right) \right] + \frac{\nu_0}{\eta^2} (\xi - \alpha) \frac{1 - e^{-\alpha t}}{1 - ge^{-\alpha t}}. \quad (3.64)$$

with $A$ and $D$ given by

$$A = \frac{A_1}{A_2}, \quad (3.65)$$

$$D = \log \alpha + \frac{(\kappa - \alpha)t}{2} - \log \left( \frac{\alpha + \xi}{2} + \frac{\alpha - \xi}{2} e^{-\alpha t} \right), \quad (3.66)$$
where $\xi$ and $\alpha$ are given by eqs.(3.37) and (3.38), respectively, and where we introduce the variables $A_1$, $A_2$, given by

$$A_1 = (u^2 + iu) \sinh \frac{\alpha}{2},$$

$$A_2 = \alpha \cosh \frac{\alpha}{2} + \xi \sinh \frac{\alpha}{2}.$$  \hfill (3.67)

With this result we are now able to find the prices of options under the Heston model for a given set of parameters $\theta$. We just need to calibrate the parameters to some market data to be able to model the volatility process.

**Negative Variance and Feller’s Condition**

One last consideration is required for the Heston model. By analyzing eqs.(3.32a) and (3.32b) we can see that the square root of the variance is used. This shouldn’t pose a problem, since the variance of any process is always positive. However, because in our case this variable is itself stochastic, we must guarantee that it doesn’t become negative, or else the square root would output imaginary numbers. To ensure this, we can apply Feller’s condition [Albrecher et al., 2007] and force the parameters to obey

$$2\kappa \nu > \eta^2.$$  \hfill (3.69)

However, this condition restricts the reachable space of our model. One possible alternative is to set the variance to zero every time it becomes negative:

$$\nu = \max \left[ \nu^*, 0 \right],$$  \hfill (3.70)

where $\nu^*$ corresponds to the unrestricted variance and $\nu$ is the new (always positive) variance, ensuring that the square root outputs a real number. Because this alternative allows any value for the parameters, it will be adopted in our implementation of the Heston model.

### 3.6.2 Static SABR Model

One other very famous model for stochastic volatility was developed by Hagan et al. [Hagan et al., 2002] and is known as SABR - we will henceforth refer to it by Static SABR, to distinguish it from the Dynamic SABR model that we will see next. SABR stands for “stochastic-$\alpha \beta \nu$” and in this model it is assumed that the option prices and volatilities follow [Vlaming, 2011]

$$dS(t) = rS(t)dt + e^{-\rho(t)(1-\beta)} \sigma(t) S(t)^{\beta} dW_1(t),$$

$$d\sigma(t) = \nu \sigma(t) dW_2(t),$$  \hfill (3.71a, 3.71b)

where we define $\alpha = \sigma(0)$ as the starting volatility and $S_0 = S(0)$ as the starting stock price. Furthermore, as before, the two Brownian motion processes $W_1(t)$ and $W_2(t)$ have a constant correlation of $\rho$. 

30
The parameters $\beta$ and $\nu$ correspond, respectively to the skewness (i.e. how the volatility smile moves when the stock price changes) and the volatility of volatility (i.e. how erratic is the volatility process).

In the original article, the authors claim that $\beta$ can be fitted from historical market data, but usually investors choose this value heuristically, depending on the type of assets traded. Typical values used are $\beta = 1$ (stochastic lognormal model), used for foreign exchange options, $\beta = 0$ (stochastic normal model), typical for interest rate options and $\beta = 0.5$ (stochastic CIR model), also common for interest rate options [Hagan et al., 2002]. Because we are trying to compare several models, no assumptions will be made on the data used. Therefore, we will leave this parameter free when fitting the model to the market data, using no heuristics.

One of the main limitations of the static SABR model is the fact that, unlike the Heston model, this stochastic volatility model is not mean-reverting. This shortcoming enables the volatility to evolve unrestrictedly, which is problematic - it may become negative, which is clearly absurd, or it may become extremely large, which is troublesome. Labordère [Labordère, 2005] proposed a mean-reverting correction to static SABR, but we will study the original model by Hagan et al., as it is more commonly used. We should still note that while negative volatilities make no sense in the real world, by examining eq.(3.71a) we can see that this should pose no problem upon simulations, since this effect would be equivalent to inverting the Brownian motion process (i.e. $dW(t) \implies -dW(t)$), which is obviously allowed.

One of the main reasons why static SABR is so popular is due to its quasi-closed-form solutions that enable us to quickly find the implied volatilities of options priced under this model. With the corrections done by Oblój on Hagan’s formula [Obloj, 2008], we can show that these implied volatilities are given by

$$
\sigma_{StatSABR}(K,f,T) \approx \frac{1}{\left[ 1 + \frac{(1 - \beta)^2}{24} \log^2 \left( \frac{f}{K} \right) + \frac{(1 - \beta)^4}{1920} \log^4 \left( \frac{f}{K} \right) \right] \cdot \left\{ 1 + T \left[ \frac{(1 - \beta)^2}{24} \frac{\alpha^2}{(Kf)^{1-\beta}} + \frac{1}{4} \frac{\rho \beta \nu \alpha}{(Kf)^{(1-\beta)/2}} + \frac{2 - 3 \rho^2}{24} \frac{\nu^2}{\alpha} \right] \right\}} \cdot \left( \frac{\nu \log (f/K)}{x(z)} \right),
$$

(3.72)

with $z$ and $x(z)$ defined as

$$
z = \frac{\nu (f^{1-\beta} - K^{1-\beta})}{\alpha (1 - \beta)},
$$

(3.73)

$$
x(z) = \log \left\{ \frac{\sqrt{1 - 2 \rho z + z^2} + z - \rho}{1 - \rho} \right\},
$$

(3.74)

where we have used $f = S_0 e^{\rho T}$. The proof of this solution is quite lengthy and will not be replicated here, though it can be found in the original article [Hagan et al., 2002].

For the particular case where $f = K$, evaluating eq.(3.72) produces a $0/0$ indeterminate form. This poses no problem because the closed form solution actually simplifies to [Hagan et al., 2002]

$$
\sigma_{StatSABR}(K, f = K, T) \approx \frac{\alpha}{K^{1-\beta}} \cdot \left( 1 + T \left[ \frac{(1 - \beta)^2}{24} \frac{\alpha^2}{K^{2(1-\beta)}} + \frac{1}{4} \frac{\rho \beta \nu \alpha}{K^{1-\beta}} + \frac{2 - 3 \rho^2}{24} \frac{\nu^2}{\alpha} \right] \right).
$$

(3.75)

As with the Heston model, we again need to calibrate the parameters of this model to be able to model the volatility process.
3.6.3 Dynamic SABR Model

One of the main setbacks of the static SABR model is the fact that it should only be calibrated and used on a set of options with the same maturity. The model behaves badly when we try to fit options with different maturities [Hagan et al., 2002].

To solve this problem, Hagan et al. suggested a similar model known as Dynamic SABR [Hagan et al., 2002]. It follows the same diffusion processes presented in eqs.(3.71a) and (3.71b) but with time-dependent parameters \( \rho(t) \) and \( \nu(t) \),

\[
\begin{align*}
    dS(t) &= rS(t)dt + e^{-r(T-t)(1-\beta)}\sigma(t)(S(t))^\beta dW_1(t), \\
    d\sigma(t) &= \nu(t)\sigma(t)dW_2(t),
\end{align*}
\]

with the correlation between \( W_1(t) \) and \( W_2(t) \) now given by

\[
dW_1(t)dW_2(t) = \rho(t)dt, \quad \forall t > 0.
\]

where \( \rho(t) \) and \( \nu(t) \) are now functions of time.

Hagan et al. derived again a quasi-closed-form solution for the implied volatilities of options priced under this model. Osajima later simplified this expression using asymptotic expansion [Osajima, 2007]. The resulting formula is given by

\[
\sigma_{\text{DynSABR}}(K,f,T) = \frac{1}{\omega} \left( 1 + A_1(T) \log \left( \frac{K}{f} \right) + A_2(T) \log^2 \left( \frac{K}{f} \right) + B(T)T \right),
\]

where \( f = S_0e^{rt} \), \( \omega = f^{1-\beta}/\alpha \) and where \( A_1(T) \), \( A_2(T) \) and \( B(T) \) are given by

\[
A_1(T) = \frac{\beta - 1}{2} + \frac{\eta_1(T)\omega}{2},
\]

\[
A_2(T) = \frac{(1-\beta)^2}{12} + \frac{1 - \beta - \eta_1(T)\omega}{4} + \frac{4\nu_1^2(T) + 3(\eta_1^2(T) - 3\eta_2^2(T))\omega^2}{24},
\]

\[
B(T) = \frac{1}{\omega^2} \left( \frac{(1-\beta)^2}{24} + \frac{\omega\beta\eta_1(T)}{4} + \frac{2\nu_2^2(T) - 3\eta_2^2(T)\omega^2}{24} \right),
\]

with \( \nu_1^2(T) \), \( \nu_2^2(T) \), \( \eta_1(T) \) and \( \eta_2^2(T) \) defined as

\[
\nu_1^2(T) = \frac{3}{T^3} \int_0^T (T-t)^2 \nu^2(t)dt,
\]

\[
\nu_2^2(T) = \frac{6}{T^3} \int_0^T (T-t)\nu^2(t)dt,
\]

\[
\eta_1(T) = \frac{2}{T^2} \int_0^T (T-t)\nu(t)\rho(t)dt,
\]

\[
\eta_2^2(T) = \frac{12}{T^4} \int_0^T \int_0^t \left( \int_0^s \nu(u)\rho(u)du \right)^2 dsdt,
\]

where \( \rho(t) \) and \( \nu(t) \) are the functions chosen to model the time dependent parameters.
We now need to empirically choose some appropriate functions for $\rho(t)$ and $\nu(t)$. We can choose these functions such that the integrals in eqs.(3.82)-(3.85) are analytically solvable, greatly simplifying the calibration of this model. Hagan et al. showed that the volatility of volatility, $\nu$, decreases with the maturity (in the Static SABR model) [Hagan et al., 2002], which seems to suggest that the function $\nu(t)$ should decrease with time. As for the correlation parameter, $\rho$, these authors claimed that its time-dependent behavior is heavily dependent on the type of underlying asset traded. Using a stock index as the underlying asset (which is also the underlying asset for which we have data, shown in Appendix A), Fernandez et al. show that this parameter decreases (in absolute value) with maturity, indicating that $\rho(t)$ also decreases (in absolute value) with time [Fernández et al., 2013]. These authors thus suggest that we define $\rho(t)$ and $\nu(t)$ as

$$ \rho(t) = \rho_0 e^{-at}, $$

$$ \nu(t) = \nu_0 e^{-bt}, $$

with $\rho_0 \in [-1, 1]$, $\nu_0 > 0$, $a > 0$ and $b > 0$. In this particular case, $\nu^2_1(T)$, $\nu^2_2(T)$, $\eta_1(T)$ and $\eta^2_2(T)$ can be exactly derived as

$$\nu^2_1(T) = \frac{6\nu^2_0}{(2bT)^3} \left[ \left( \frac{(2bT)^2}{2} - 2bT + 1 \right) - e^{-2bT} \right],$$

$$\nu^2_2(T) = \frac{12\nu^2_0}{(2bT)^4} \left[ e^{-2bT}(1 + bT) + bT - 1 \right],$$

$$\eta_1(T) = \frac{2\nu_0\rho_0}{T^2(a + b)^2} \left[ (a + b)T + e^{-(a+b)T} - 1 \right],$$

$$\eta^2_2(T) = \frac{3\nu^2_0\rho^2_0}{T^4(a + b)^3} \left[ e^{-2(a+b)T} - 8e^{-(a+b)T} + (7 + 2T(a + b)(-3 + (a + b)T)) \right].$$

There are other possible functions for $\rho(t)$ and $\nu(t)$. An example of such functions can be found in Fernandez et al. [Fernández et al., 2013]. The main concern with these functions is that they usually don’t have analytically solvable solutions for the integrals in eqs.(3.82)-(3.85), and these integrals need to be computed numerically, which greatly increases computation time. For this reason, they will not be considered in the present work.
Chapter 4

Implementation

To apply the models described before, we first need to train them on some real data. This training enables us to adapt each of our models to real market conditions, allowing us to forecast, to some extent, how the volatility of some real stock will behave in the future. This training procedure will be explained in the next sections.

Having trained our models, we should be able to price any option, using some numerical algorithms, which we will approach at the end of this chapter.

4.1 Surface Interpolation (Dupire model)

To apply Dupire's local volatility model, as shown in eq.(3.27), we need to generate the implied volatility surface from the market data. Because we only have data for a finite set of maturities and strikes, the implied volatility surface must be obtained with some form of interpolation and extrapolation. From this interpolated surface we must also calculate the gradients needed for the local volatility formula.

One possible interpolation method is known as Delaunay triangulation [Amidror, 2002]. In short, assuming a 2-dimensional data set, this interpolation algorithm generates a triangulation between points $P_1$, $P_2$ and $P_3$ if the circumscribed circle of these points contains no other points $P_j$ inside. A scheme of this interpolation method is shown in Figure 4.1.

Figure 4.1: Example of a Delaunay triangulation, where we connect the points for which the circumscribed circles (green) do not contain any other points inside. A circle for which this property does not hold (orange dashed) is also represented, though no triangulation is possible in this case.

Adapted from: https://www.ti.inf.ethz.ch/ew/Lehre/CG13/lecture/Chapter%206.pdf
We can easily adapt this algorithm to 3-dimensions (as is the case of our data), using spheres instead of circles. The resulting interpolated surface will simply be a set of merged triangles, with the data points serving as vertices. Though this is usually a good approximation, it will produce wrong results when calculating the derivatives used in the local volatility formula (i.e. calculating the second derivative on the triangular planes of the interpolation results in zero, since the gradient of a plane is constant). If we used the first version of Dupire’s formula, shown in eq.(3.10), where we use the second derivative in the denominator, the resulting local volatility surface would become highly unrealistic. However, since we will use the formula in eq.(3.27), which is not so sensitive to this value, no significant problems are expected.

The function `scatteredInterpolant`, implemented in MATLAB, applies this Delaunay triangulation to a set of scattered data, and will therefore be used in the implied volatility surface generation. With this function we are also able to perform extrapolation, which is important, since during the simulations it is possible that some of the paths reach prices above/below the highest/smallest strikes for which we have data. This extrapolation is done by calculating the surface gradient at the interpolation boundary and assuming that these gradients remain constant outside the boundary, thus extending the surface [MATLAB, a].

From the interpolated surface obtained, we need to extract the gradients to be able to use Dupire’s formula. These have to be obtained numerically, as we do not have an analytical formula for the surface. To obtain them we use the formulas

\[
\frac{\partial \sigma_{imp}}{\partial K} = \frac{\sigma_{imp}(K + \Delta K, T) - \sigma_{imp}(K - \Delta K, T)}{2\Delta K}
\]

\[
\frac{\partial^2 \sigma_{imp}}{\partial K^2} = \frac{\sigma_{imp}(K + \Delta K, T) + \sigma_{imp}(K - \Delta K, T) - 2\sigma_{imp}(K, T)}{(\Delta K)^2}
\]

\[
\frac{\partial \sigma_{imp}}{\partial T} = \frac{\sigma_{imp}(K, T + \Delta T) - \sigma_{imp}(K, T)}{\Delta T}
\]

where \(\Delta K\) and \(\Delta T\) are some (small) intervals for the strike and maturity, respectively. Note that the derivative of the implied volatility w.r.t. maturity is different from the derivative w.r.t. strike. This is due to the fact that negative maturities make no mathematical sense. If we used the same formula as for the derivative w.r.t. the strikes, the case of \(T = 0\) would require \(\sigma_{imp}(-T - \Delta T < 0)\), which makes no sense. We thus use the forward derivative in this case, as shown in eq.(4.1c). As for the strikes, since there is no mathematical restriction for negative values (though they make no sense in financial terms), we are allowed to use both \(\sigma_{imp}(K \pm \Delta K, \cdot)\).

Having interpolated the implied volatility surface and obtained all the required gradients, we are able to generate the local volatility surface. To do this, we evaluate the interpolated implied volatility surface and all the required gradients at multiple points \(K_j, T_i\) to produce multiple local volatility values \(\sigma(K_j, T_i)\) with eq.(3.27). The points should be uniformly spaced in a grid. Interpolating between these grid points with Delaunay’s triangulation we are able to generate a surface for \(\sigma(K, T)\). We now simply need to make a variable change \(\sigma(K, T) \Rightarrow \sigma(S, t)\) to be able to properly obtain the local volatility surface, as presented in Figure 3.6.
4.2 Model Calibration (Heston and SABR models)

Both SABR and Heston stochastic volatility models contain parameters that need to be calibrated to appropriately replicate market option prices.

Calibrating the models’ parameters means finding the optimal values for these parameters such that the difference between the prices of real market options and the prices of options under each of the models’ assumptions is minimized. However, because we are modeling volatilities, it is more appropriate to minimize the difference between the implied volatilities of market options and options priced under each model.

4.2.1 Cost Function

This difference should be measured with a cost function, which we have to minimize, such as the least-squares error, given by

\[
\text{Cost}(\theta) = \sum_{i=1}^{n} \sum_{j=1}^{m} w_{i,j} (\sigma_{\text{imp.mkt}}(T_i, K_j) - \sigma_{\text{imp.mdl}}(T_i, K_j; \theta))^2 ,
\]

where we denote \( \theta \) as the model's parameter set, \( w_{i,j} \) corresponds to some weight function and where \( \sigma_{\text{imp.mkt}}(\cdot) \) and \( \sigma_{\text{imp.mdl}}(\cdot) \) correspond to the real-market and the model's implied volatilities, respectively, for maturities \( \{T_i, i = 1, \ldots, n\} \) and strikes \( \{K_j, j = 1, \ldots, m\} \). This will be the cost function used in the calibration of the stochastic volatility models.

Weight function

The weight function \( w_{i,j} \) should be chosen such that higher weights are given to options with strikes closer to the current stock price \( S_0 \), because these points have a higher influence in the shape of the volatility smile than the others. One example of such a function is

\[
w_{i,j} = \left(1 - \left| 1 - \frac{K_j}{S_0} \right| \right)^2 ,
\]

where we assume strikes are restricted to \( K < 2S_0 \). This function is represented in Figure 4.2. Many other possible weight functions are also possible, taking into account the maturity date, for example, but no other weight functions will be considered.

As we can see, the maximum weight value is given to the point where the strike equals the initial stock price \( K = S_0 \) and less weight is given for points farther from this value.

Using the Closed-Form Solutions

To find the cost value of any given set of parameters we need first to price the options under each model using those parameters. This could be done using some numerical method, such as Monte Carlo simulation, which we will approach in the next section. However, such methods are usually relatively
slow to execute and using them to calibrate the models (which requires a large number of options to be priced) would become too cumbersome.

Fortunately, as we mentioned before, both Heston and SABR have closed-form solutions, shown in eqs. (3.33), (3.72) and (3.78), that we can use to directly price the options with each model’s parameters, without the need to run any slow numerical pricers. With these closed-form solutions, we are able to find the prices and respective implied volatilities extremely fast, which is extremely useful. The optimization algorithms should then have no problem in finding optimal solutions for each model’s parameters.

4.2.2 Optimization Algorithms

There are many optimization algorithms able to find the parameter set that minimizes the cost function shown in eq.(4.2). Our main concern when choosing the best algorithm for this calibration is the nonlinearity of our cost function. This is problematic because several local minima might exist, and an unsuitable algorithm might get stuck in these points, causing the globally optimal solution to not be found.

With this issue in mind, we selected a powerful algorithm known as CMA-ES [Hansen, 2006] (short for Covariance Matrix Adaptation Evolution Strategy), which we will summarize below. It should be noted that we will only provide a general idea of how this optimizer works. For detailed descriptions, the original source should be consulted.

The optimization algorithm will search the $D$-dimensional sample space for the optimal solution, $\theta^*$, where $D$ denotes the number of parameters of each model. Each point in this space corresponds to a possible set of parameters, $\theta$. 
CMA-ES Optimizer

The CMA-ES optimizer belongs to the class of evolutionary algorithms. These methods are based on the principle of biological evolution: at each iteration (generation), new candidate solutions (individuals) are generated from a given random distribution (mutation) obtained using the data (genes) of the previous solutions (parents). Of these newly generated solutions (individuals), we select the ones where the cost function is minimized (with the best fitness) to generate the candidate solutions of the next iterations (to become the parents of the next generation) and we reject the others.

As for the CMA-ES in particular, the algorithm takes \( \lambda \) samples from a multivariate normal distribution in the \( D \)-dimensional sample space, i.e. \( x \sim N(m, C) \), with density function given by

\[
N(x; m, C) = \frac{1}{\sqrt{(2\pi)^D|\det C|}} \exp \left( -\frac{1}{2} (x - m)^T C^{-1} (x - m) \right), \tag{4.4}
\]

where \( m \) and \( C \) correspond to the distribution’s mean vector and covariance matrix, respectively. These \( \lambda \) samples are our candidate solutions.

We classify each of these points according to their fitness (i.e. the cost function’s value for a given point). We then select the \( \mu \) samples with the lowest cost and discard the others. These new points will be the parents of the next generation, i.e. they will be used to generate the new mean and covariance matrix for the normal distribution.

At each iteration, the new mean is produced from a weighted average of the points, with the weights proportional to each point’s fitness. The method for the covariance matrix update is rather complex and depends not only on the \( \mu \) best samples but also on the values of the covariance matrices used in previous iterations. All the basic equations required for the implementation of this optimizer can be found in Appendix B. For a more detailed explanation, as well as other aspects of the algorithm, see Hansen [Hansen, 2016].

These sampling-classification-adaptation steps are repeated until some stopping criterion is met, such as a fixed number of iterations or a minimum error threshold. When this stopping criterion is verified, the mean vector of the last iteration is assumed as the optimal parameter vector, \( \theta^* \).

The number of candidate solutions generated at each step, \( \lambda \), and the ones that remain after classification, \( \mu \), can be chosen arbitrarily, but an adequate heuristic is to choose \( \lambda = \lceil 4 + 3 \log D \rceil + 1 \) and \( \mu = \lfloor \lambda/2 \rfloor + 1 \).
This optimization procedure is summarized in Algorithm 1.

**Algorithm 1: CMA-ES Optimizer**

Define mean vector $\mathbf{m} = \theta_0$  
/* Initial guess */

Define covariance matrix $\mathbf{C} = I$

while Termination criterion not met do

Sample $\lambda$ points from multivariate normal distribution $\mathcal{N}(\mathbf{x}; \mathbf{m}, \mathbf{C})$

Calculate the cost for all generated points and keep the $\mu$ best. Discard the rest

Update the mean vector and covariance matrix (using eqs.(B.5) and (B.9))

end

Optimal parameters: $\theta^* = \mathbf{m}$

The complexity of the covariance matrix updating process makes the CMA-ES a very robust optimization algorithm, enabling it to find the global optimum of highly nonlinear functions [Dilão and Muraro, 2013]. Furthermore, unlike many other optimizers, the CMA-ES is almost non-parametric. It simply requires a starting guess, to generate the starting mean vector, and the algorithm is expected to converge to a global minimum. As for disadvantages, because we have to generate a set of samples at each iteration, if this generation process is slow (which isn’t our case, because we use the closed-form solutions to price options), the convergence may stall significantly, particularly when many parameters are used in the model. Other algorithms may perform faster than CMA-ES, but this optimizer is expected to outperform them in terms of precision.

This optimizer was implemented by Hansen in MATLAB (as well as in other computer languages) as a function named `purecmaes` [Hansen, 2014] and will be used almost unchanged (with only very slight changes, to account for the volatility models used used).

We should note that several other optimization algorithms were used, namely Simulated Annealing [MATLAB, e], Multi Start [MATLAB, c], Pattern Search [MATLAB, d] and Genetic Algorithm [MATLAB, b], all implemented in MATLAB, but CMA-ES not only greatly outperformed them in terms of accuracy, always finding lower cost values that the others, but often also in terms of computation time. For this reason, we chose CMA-ES for all implementations.
4.3 Numerical Option Pricing

Having trained all the models on some real market data, we should now be able to price any European
options. These contracts only account for a share of the market, though, and the closed form solutions
introduced before don’t apply to Exotic options, which are also quite important. We thus need some
numerical method to price such contracts.

Currently, the two most used methods to computationally price options are known as finite differ-
ences [Hull, 2009] and Monte Carlo [Glasserman, 2004].

The finite differences method is an extremely fast procedure when used to price either European or
American-type options, making it very appealing in these circumstances. However, when we increase
the dimensionality of the problem (i.e. the number of underlying independent variables, such as $S$ and $t$),
such as when dealing with options whose payoff depends on the past history of the stock price (e.g.
Asian options, which are derivatives that depend on the average value of the stock price until maturity),
the algorithm requires some considerable modifications that make it slower and more complex, which is
why we will not cover it in this thesis. The implementation of both Heston and SABR models (presented
before) using finite differences can nonetheless be found in deGraaf [de Graaf, 2012].

With the Monte Carlo algorithm, we begin by simulating a very large number of stock price paths
(e.g. 100,000 simulations). The option’s payoff is then calculated for each of these simulated paths
and averaged, providing a fairly good estimate of the option’s future payoff. The option’s price can be
extracted from its expected payoff, using eq.(2.3). This algorithm can be easily adapted to price path-
dependent options, making it very attractive in such cases. In the past, simulating all the stock price
paths took prohibitively long computation times and this method was often discarded for this reason.
However, with the recent advancements in computer hardware and new algorithmic developments, such
as GPU implementation, this shortcoming has been, to some extent, mitigated, making the Monte Carlo
algorithm quite popular in the present. For these reasons, the Monte Carlo method will be used for the
implementation and analysis of the models introduced in chapter 3, so this model will be studied to some
extent in the present chapter.

4.3.1 Simulating stock prices

As stated, to implement the Monte Carlo algorithm, one needs to simulate stock price paths. However,
by analyzing eq.(2.14), we can see that the stock prices depend on a Brownian motion process which,
due to its self-similarity, is not differentiable [Mikosch, 1998]. It follows that stock price paths can never be
exactly simulated. Despite this, we can approximate the movement of stock price paths by discretizing
the Brownian motion process in time, avoiding its self-similarity problem. We now introduce two of the
most common discretization procedures.
**Euler–Maruyama discretization**

One of the simplest and most used discretization methods is known as *Euler–Maruyama discretization*, which can be applied to stochastic differential equations of the type

\[
dX(t) = a(X(t))dt + b(X(t))dW(t),
\]

(4.5)

where \(a(X(t))\) and \(b(X(t))\) are given functions of the stochastic variable \(X(t)\) and where \(\{W(t), \ t > 0\}\) defines a one-dimensional Brownian motion process. To apply this discretization, we begin by partitioning the time interval \([0, T]\) into \(N\) subintervals of width \(\Delta t = T/N\) and then iteratively defining

\[
X_{n+1} = X_n + a(X_n)\Delta t + b(X_n)\Delta W_n, \quad n = 1, \ldots, N,
\]

(4.6)

with \(X_0\) equal to the initial value of the stochastic variable \(X(t)\) and where \(\Delta W_n = W(t + \Delta t) - W(t)\). Using the known properties of Brownian motion processes, it can be shown that \(\Delta W_n \sim \sqrt{\Delta t}Z(t)\), where \(Z(t) \sim N(0, 1)\) defines a normal distributed random variable [Mikosch, 1998].

Applying this discretization to the Geometric Brownian motion followed by stock price paths, as seen in eq.(2.14), we arrive at

\[
S(t + \Delta t) = S(t) + rS(t)\Delta t + \sigma(S(t), t)S(t)\sqrt{\Delta t}Z(t).
\]

(4.7)

Due to its simplicity, the Euler–Maruyama discretization method is the most common in the simulation of stock price paths whenever we have constant or deterministic volatilities.

When using the constant volatility model, we simply need to replace \(\sigma(S(t), t)\) by a constant \(\sigma\) and we can easily generate the GBM. As for Dupire’s local volatility, to simulate a stock price path we need to sample the local volatility surface at the point \(\sigma(S_i, t_j)\) when we are at the time step \(t_j\) of the simulation with a stock price \(S_i\) and assume that value as the local volatility, to be used on the generation of the next stock price value, \(S_{i+1}\). We iterate this procedure for all time steps until we reach the maturity.

**Milstein Discretization**

For stochastic volatility models, such as Heston and SABR, where the volatility itself follows a stochastic process, the Euler–Maruyama discretization may not be sufficiently accurate. In these cases, we can apply the more precise Milstein method [Milstein, 1975], defined as

\[
X_{n+1} = X_n + a(X_n)\Delta t + b(X_n)\Delta W_n + \frac{1}{2} b'(X_n)b''(X_n)((\Delta W_n)^2 - \Delta t),
\]

(4.8)

where \(b'(X_n)\) denotes the derivative of \(b(X_n)\) w.r.t. \(X_n\). Note that when \(b'(X_n) = 0\) (i.e. the volatility doesn’t depend on the stock price), the Milstein method degenerates to the simpler Euler–Maruyama discretization. This discretization should be applied not only to the stock price process but also to the stochastic volatility.
Applying this discretization to the stock price and variance processes of the Heston model produces

\[ S(t + \Delta t) = S(t) + rS(t)\Delta t + S(t)\sqrt{\nu(t)}\Delta t((Z_1(t))^2 - 1), \quad (4.9) \]

\[ \nu(t + \Delta t) = \nu(t) + \kappa(\bar{\nu} - \nu(t))\Delta t + \eta\sqrt{\nu(t)}\Delta t((Z_2(t))^2 - 1), \quad (4.10) \]

where \( Z_1 \) and \( Z_2 \) are two normal random variables with a correlation of \( \rho \).

As for the SABR model, this discretization results in

\[ S(t + \Delta t) = S(t) + rS(t)\Delta t + e^{-r(T-t)}(1-\beta)\sigma(t)S^\beta(t)\sqrt{\Delta t}(Z_1(t)) + \frac{\beta}{2}e^{-2r(T-t)(1-\beta)}\sigma^2(t)S^{2\beta-1}(t)\Delta t((Z_1(t))^2 - 1), \quad (4.11) \]

\[ \sigma(t + \Delta t) = \sigma(t) + \nu\sigma(t)\sqrt{\Delta t}(Z_2(t)) + \frac{\nu^2}{2}\sigma(t)\Delta t((Z_2(t))^2 - 1). \quad (4.12) \]

For the Dynamic SABR model, the discretization is the same as its Static equivalent, replacing only the variables \( \nu \) and \( \rho \) with the functions \( \nu(t) \) and \( \rho(t) \), respectively.

In all these models we need to generate two correlated normal variables, \( Z_1(t) \) and \( Z_2(t) \), with a correlation of \( \rho(t) \). This can be easily achieved using

\[ Z_1(t) \sim N(0,1); \quad (4.13a) \]

\[ Z_2(t) = \rho(t)Z_1(t) + \sqrt{1-(\rho(t))^2}Y(t), \quad (4.13b) \]

where \( Y(t) \sim N(0,1) \) is a random variable independent of \( Z_1(t) \).

Because it is more precise, the Milstein method will be used in the implementation of the Heston and Static/Dynamic SABR stochastic volatility models. The simpler Euler–Maruyama discretization will be assumed for both constant and Dupire’s local volatility.

To generate a stock price path in both the Heston and SABR models, at each time step we have to solve eqs.(4.9)-(4.12), obtaining the values of \( S(t + \Delta t) \) and \( \sigma(t + \Delta t) \), which we will use in next time step as \( S(t) \) and \( \sigma(t) \). We iterate this procedure until we reach the maturity.

It is important to note that, the smaller our subintervals \( \Delta t \) are, the better is the approximation done when discretizing the Brownian motion process. However, by decreasing \( \Delta t \) we increase the number of intervals needed and, with it, the number of calculations required to generate a stock price path. This compromise between computation time and precision must be handled appropriately. In Figure 4.3 we can see how the size of the subintervals influences the resemblance of a simulated GBM process to its “continuous” version.

We should also note that this discretization is more problematic when we try to price Barrier options. As we stated before, a Barrier option becomes activated/void if the stock price reaches a certain barrier level \( B \). When we discretize a continuous stock price process, we ignore any prices that this process might have taken in the period between two time steps. However, it is perfectly possible that during this interval the real stock price goes below/above this barrier level and back up/down, which is not
Figure 4.3: Effect of the size of the subinterval $\Delta t$ on the GBM discretization, with maturity $T = 1$ yr, interest rate $r = 0.01$ yr$^{-1}$, volatility $\sigma = 0.1$ yr$^{-1/2}$ and initial stock price $S_0 = 1$€. To emphasize this effect, the underlying Brownian Motion $\{W(t), \ t > 0\}$ used to generate all three paths was the same.

considered in the discretization. A barrier option might have crossed a barrier with a non-discretized Geometric Brownian motion process and not with its discretization. Thus, Barrier options will always be underpriced or overpriced (depending on the type of barrier contract) when the Monte Carlo method is used. This problem can be mitigated by significantly increasing the number of time steps, reducing their size, though this will increase computation time. Furthermore, reducing the step size merely diminishes the severity of the problem and doesn’t actually solve it.

### 4.3.2 Pricing options from simulations

Now that we are able to simulate stock prices, to price options using the Monte Carlo algorithm, we generate $M$ paths by recursively calculating $\{S_i(t_j), \ i = 1, \ldots, M, \ t_j = 0, \ldots, T\}$, using either of the discretization methods described before.

When the stock price at the maturity, $S_i(T)$, is obtained for all paths, the option’s payoff for each path is calculated using eqs. (2.1)-(2.2). We then average all these results and discount them back to the present, obtaining the option’s value

$$C(K,T) = e^{-rT} \frac{1}{M} \sum_{i=1}^{M} \text{Payoff}_{i,\text{call}}(K,T); \quad (4.14a)$$

$$P(K,T) = e^{-rT} \frac{1}{M} \sum_{i=1}^{M} \text{Payoff}_{i,\text{put}}(K,T), \quad (4.14b)$$

where $\text{Payoff}_{i, \ (K,T)}$ denotes the payoff function of the chosen option type (e.g. European, Barrier, ...) for the $i^{th}$ path.

The payoff function of a European option is quite trivial to obtain, we simply need to apply eq.(2.1) to
the stock price at maturity of each simulation. Pricing barrier options is only very slightly more complex: besides applying the discretization methods described before, we are also required to check at all simulation time steps whether each stock price process crossed the barrier level or not and, at the maturity, only use those that did to calculate the option price using eq.(2.2).

Despite its versatility, the Monte Carlo method can lead to an erroneous estimate for the price of options, particularly for European call options with very high strike prices or puts with very low strikes. To understand this problem, notice that the payoff function of European call options is zero for stocks below the strike. If we have a very large strike, very few of the simulated paths will actually cross the strike at maturity and contribute to the calculation of the option's price (all the other paths will contribute with a payoff of zero). The averaging procedure shown in eq.(4.14) will therefore be performed on an extremely small subset of paths, thus producing a very rough estimation for the option price. We could counter this effect by simulating an even larger number of paths, so that we always have a significant number of paths above any given strike contributing to the option's price, though this comes at the cost of increased computation times. Furthermore, on the limit, there will always be a strike high enough that none of the simulated paths reach it, meaning that the option's value for that simulation would be zero. This does not hold in real life, since there is always a non-zero price for any option, even for extremely high strikes. This problem is further aggravated for Barrier options, since only the paths that are above the strike price at maturity and have crossed the barrier level contribute to the option price. This further limits the subset of paths considered and is quite problematic for high barrier levels.

In short, the Monte Carlo method is very simple and quite versatile, though it must be used with some care to work properly.
Chapter 5

Results

Having described the implementation of all the models introduced in chapter 3 and the calibration and interpolation methods referenced in chapter 4, in this chapter we study the results of the calibration and compare all the models and respective simulations.

We will calibrate the SABR and Heston models' parameters with a dataset of implied volatilities for European options with different maturities and strike prices. This data is shown in Appendix A. As stated before, the closed form solutions will be used in this calibration procedure. After the calibration, we are able to produce a function from these closed-form solutions that relates the strike price with the implied volatility, using the models' calibrated parameters. This function - henceforth named theoretical function - should, in principle, closely fit the implied volatility data.

To validate the SABR and Heston models' closed-form solutions, after finding the optimal parameters with the calibration procedure, we will input them into a Monte Carlo pricer, adapted to each model, and calculate the simulated option prices of each calibrated model. This price will then be converted into an implied volatility (using eq.(3.5)) for the simulation to be comparable to the data and the theoretical function. To better grasp the behavior of the simulations we will repeat them a large number of times, $N_{\text{reps}}$, averaging the results to produce a function also relating the strike price with the implied volatility - henceforth named simulated function - and extracting from them the 95% confidence bands of the simulations - these confidence bands are obtained by sorting the simulated implied volatilities for each strike, and then extracting both the 97.5% highest and the 2.5% lowest, using these values as the upper and lower bounds of the confidence bands, so that 95% of all observations are contained between them.

As for Dupire's local volatility data, the required Delaunay triangulation introduced in section 4.1 will be performed on the aforementioned data. The resulting interpolation will be used to obtain the local volatility surface, which will be input into a Monte Carlo pricer to generate the option price under this model's assumptions. As done for the Heston and SABR models, we will run this pricer a large number of times, $N_{\text{reps}}$, to obtain the average simulated function and the 95% confidence bands. Because no closed-form solutions exist for this model, no theoretical functions will be displayed in this case.

For the models to be comparable, we need to make sure that the same global parameters are used in all the adjustments and simulations, namely the initial stock price, $S_0$, the risk-free interest rate, $r$, the
number of Monte Carlo pricer repetitions (to be averaged, producing the expected simulated function and the confidence bands), \( N_{\text{reps}} \), and the time step size and the number of paths simulated, \( \Delta t \) and \( N_{\text{paths}} \), both used in the Monte Carlo simulations. Their values are shown in Table 5.1.

Table 5.1: Global parameters used throughout all simulations.

The Monte Carlo pricers of each model will then be modified to price Barrier options instead of the European options used in the calibration. These results will be studied with some detail but, due to a lack of real market data, there is no way to corroborate their validity.

As a side note, we should also point out that, for the maturities, we used the typical market convention of defining a month as having only 21 days, to account only for the days when exchanges are open. Thus, we assume that a year has 252 (open market) days.

### 5.1 Constant Volatility Model

To find how well our models perform, we need some reference against which to compare them. One clear possibility is to assume a constant volatility throughout the options’ duration, since this is the simplest possible case - any other model should be able to outperform this one.

The equation that generates each stock price path is therefore given by

\[
dS(t) = rS(t)dt + \sigma S(t)dW(t).
\]  

(5.1)

With this constant volatility model, we can choose to fit the datasets with different maturities independently of one another or together as an ensemble. In other words, we can do several independent fits, one for each maturity, or a single ensemble fit, for all maturities together. The former will be useful when benchmarking the Static SABR model, since for that model the adjustments will also be performed independently (Static SABR performs badly for multiple maturities). The latter will be more appropriate when studying the remaining models - Dupire, Heston and Dynamic SABR - since these fit the whole implied volatility surface (i.e. multiple maturities together). Thus, both versions will be implemented and briefly studied. To clarify, we will still represent all maturities for both adjustment types (independent/dependent), but in the independent case the fits will be done independently for each maturity - a different (constant) implied volatility will be fitted for each maturity - and in the dependent case a single implied volatility will be fitted to the whole ensemble.
5.1.1 Independent Fits

We begin by presenting the results of fitting a constant volatility function to the sets of data with different maturities *independently*.

In Figure 5.1 we show the plots of each fitted implied volatility curve - the *theoretical functions* - along with the provided market data. We also present the results of the Monte Carlo pricer - the *simulated functions* - and the simulations’ confidence bands.

![Figure 5.1: Implied volatility functions (red lines) fitted independently to the implied volatility data (crosses) for different maturities under constant volatility model, plotted with their respective Monte Carlo simulated functions (light-blue dot-dashed lines) along with their 95% confidence bands (blue region).](image)

(a) $T = 21$ days  
(b) $T = 42$ days  
(c) $T = 63$ days  
(d) $T = 126$ days
The fitted parameter, which, in this case, is only the constant implied volatility, is presented in Table 5.2 for each of the maturities, along with the respective cost function's value (eq.(4.2)).

Table 5.2: Fitted implied volatilities for each maturity (fitted independently) under constant volatility model.

By observing the fit results in Table 5.2 we see that the cost function decreases with the maturity. This is indeed what is expected, since the implied volatility surface becomes flatter as maturity increases, as can be seen from the market data (and also as we can see in Figure 3.3). This makes the constant volatility function a better approximation in such cases, which decreases the cost function's value.

We should note that the fitted constant implied volatilities' values are typical for what is usually observed in the market, i.e. values around \(0.25\text{yr}^{-1/2}\).

One other property that we can observe is that the constant implied volatility also decreases with maturity. The reason behind this is the simple fact that earlier maturities contain higher implied volatilities (for the strikes far from \(S_0\)), which pull the fitted constant volatility function upwards.

We now focus on the results presented in Figure 5.1. First, we can see that the theoretical functions (full red lines) clearly don't represent the market data. This is indeed what is expected, since the constant volatility model doesn't cover the volatility smile phenomenon, which we explained before.

Secondly, by comparing the theoretical and simulated functions, we must note that the simulation performs extremely well for strikes near \(S_0\). Notice that the simulated function (dot-dashed blue line) perfectly follows the constant volatility theoretical result (full red line) in this region, and that the confidence bands converge to the simulated function indicating that all simulations produced the same result. This seems to suggest that the simulation is working as expected for this particular region.

Thirdly, we notice that on the earliest maturity (i.e. 21 days), for strikes much larger than \(S_0\) (e.g. \(K/S_0 = 1.5\)), the simulated implied volatilities go to zero, even though they should remain constant. The reason behind this has already been discussed in subsection 4.3.2 and relates to the very, very small number of paths that reach such high strikes and end up contributing to the option price (which is then converted to an implied volatility). For the case of strike \(K/S_0 = 1.5\), and maturity \(T = 21\) days, under this constant volatility model the number of paths that reach the strike is indeed approximately 0.25 out of 100000 (i.e. one out of four Monte Carlo simulations of 100000 paths contains a single path that is able to reach such a high strike). This problem is not observed on the remaining maturities for the simple reason that, because they are given more time to evolve, more paths are able to reach these high strikes and contribute to the option price. To solve this problem, we could significantly increase the number of simulations, so that the number of paths that are able to reach these high strikes is enough to produce a good estimate of the option price. The problem with this solution is the very significant increase in the...
computation time required, which makes it impractical. If we lowered the number of simulated paths from 100,000 to any other smaller amount, the problem described before would become even more severe, and the later maturities would eventually also display the problem observed in the earliest maturity.

Finally, we must discuss the large confidence bands for strikes much lower than $S_0$ (e.g. $K/S_0 = 0.5$), occurring over all maturities. To explain this, we require the points made in section 3.4, particularly for Figure 3.5, where we introduced the concept of relative change of the option price w.r.t. the volatility. Repeating the example from before, a relative change of 5 means that a variation of 1% in the volatility will produce a variation of 5% in the option price. We saw that for low strikes, this quantity was extremely small. This means that the option price is very insensitive to the volatility (i.e. a change in the volatility barely affects the price), but it also means that the volatility is very sensitive to the option price (i.e. a small change in the price significantly affects its implied volatility). The reason why this observation is important here is because we are calculating option prices from simulations and then converting them to implied volatilities (solving eq.(3.5)). Even though the Monte Carlo pricer is expected to produce a very good estimation of option prices with lower strikes (a very large number of paths contribute to the option price, so the estimation will be very accurate, with very little variation - the opposite of what we described before for high strikes), because there will always be some variation on different simulations, the pricer is expected to produce some very slightly different results when executed multiple times, which is enough to cause some of the generated implied volatilities to differ significantly from one another, some going to approximately zero others increasing significantly, which explains the large confidence bands. This is not observed in the higher strikes because the value of relative change is very small. Furthermore, in the low strike regions, we can see that the confidence bands seem to decrease in size for the higher maturities. This phenomenon was also expected from the conclusions made in Figure 3.5, where we noted that the relative change decreased with the maturity, which attenuates the severity of the problem posed before.

These two last problems are not only applicable to the constant volatility model and will also be observed in all the other models, as we shall see next.
In Table 5.3 we show the values of the implied volatilities fitted to the data for the different maturities, along with their relative errors when compared to the provided implied volatility data, shown in Table A.1. We also show the respective European option prices of said fitted volatilities and their corresponding relative errors (when compared to the option prices of the provided data, also in Table A.1).

|            | 1.50    |                               | 0                     | 8.510 \times 10^{-4} | 1            |

Table 5.3: Fitted implied volatilities (fitted independently) and respective option prices along with their corresponding relative errors w.r.t. the provided data under the constant volatility model.

One interesting property that we can extract from the data in Table 5.3 is that the relative errors of the option prices, Error$_C$, seem to increase with the strike. This is indeed expected from the conclusions obtained in section 3.4: we saw that options with high strikes had a higher relative change on the option price w.r.t. the volatility. This means that a small (relative) variation in the implied volatility causes a very considerable (relative) change in the option price. Observing, for example, the data for the strike $K/S_0 = 1.25$ and the maturity $T = 21$ days, we see that even though the relative error for the implied volatility is only 18%, the resulting relative error on the option price is 368%, which is a staggering
difference. On the other hand, we also saw that for options with low strikes the value of relative change was small, which means that even large (relative) changes in the implied volatility barely affect the price. Observing now, for example, the data for the strike $K/S_0 = 0.75$ on the same maturity, the relative error on the implied volatility is 55%, significantly higher than before, but the respective relative error on the option price is 0% (rounded off to the units).

Furthermore, we noted in section 3.4 that the value of relative change for strikes $K/S_0 = 1$ was approximately 1 throughout all maturities. This would mean that for such strikes, the relative errors in the implied volatility would be approximately the same as the relative errors in the option price, which is precisely verified in the data throughout all maturities (see, for example, the relative errors of 14% in both the implied volatility and option price for the maturity $T = 63$ days and strike $K/S_0 = 1$).

Finally, it is clear that the relative errors of the option price decrease with the maturity (e.g. for the maturity of 21 days we have errors up to 368%, whereas for the maturity of 63 days they only go up to 85%). This phenomenon was also expected from the conclusions made before, where we noted that the relative change decreased with maturity, which attenuates the high relative change phenomenon.

We can thus conclude that the results corroborate what would be expected from our predictions.
### 5.1.2 Dependent Fits

We now present the results obtained from fitting constant volatility function to the ensemble with all implied volatility data, regardless of maturity.

In Figure 5.2 we show the theoretical and simulated functions as well as the provided market data.

![Figure 5.2: Implied volatility functions (red lines) fitted simultaneously to the implied volatility data (crosses) for different maturities under constant volatility model, plotted with their respective Monte Carlo simulated functions (light-blue dot-dashed lines) along with their 95% confidence bands (blue region).](image)

The fitted implied volatility is represented in Table 5.4 as well as the cost function’s value.

<table>
<thead>
<tr>
<th>$\sigma_{imp, mdl} \ (yr^{-1/2})$</th>
<th>Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.2838</td>
<td>0.1248</td>
</tr>
</tbody>
</table>

Table 5.4: Fitted implied volatility for all maturities (fitted simultaneously) under constant volatility model.

Regarding the plots in Figure 5.2 they look very similar to those in Figure 5.1, so not much more can be added regarding their analysis.

As before, we now show the fitted implied volatility and its corresponding option prices as well as their relative errors when compared against the data in Table A.1.
Table 5.5: Fitted implied volatilities (fitted simultaneously) and respective option prices along with their corresponding relative errors w.r.t. the provided data under the constant volatility model.

As before, the relative errors of the option prices seem to increase with the strike, even though the same behavior is not observed for the relative errors of the implied volatilities, which has already been discussed.
5.2 Dupire Model

The stochastic differential equation for the stock price paths under the local volatility model was hypothesized to be given by

$$dS(t) = rS(t)dt + \sigma(S(t), t)S(t)dW(t),$$

(5.2)

where $\sigma(S(t), t)$ can be obtained through Dupire’s model, defined in subsection 3.5.1, which is given by

$$\sigma(S(t), t) = \frac{\sigma_{imp}^2 + 2t\sigma_{imp} \frac{\partial \sigma_{imp}}{\partial T} + 2r(S(t))t\sigma_{imp} \frac{\partial \sigma_{imp}}{\partial K}}{\sqrt{1 + (S(t))d_1 \sqrt{t} \frac{\partial \sigma_{imp}}{\partial K}^2} + (S(t))^2 t\sigma_{imp} \left( \frac{\partial^2 \sigma_{imp}}{\partial K^2} - d_1 \left( \frac{\partial \sigma_{imp}}{\partial K} \right)^2 \sqrt{t} \right)},$$

(5.3)

where $d_1$ is defined as

$$d_1 = \log(S_0/S(t)) + \left( r + \frac{1}{2}\sigma_{imp}^2 \right) t \sigma_{imp} \sqrt{t}.$$  

(5.4)

As we mentioned in section 4.1, we must produce the implied volatility surface from the market data using an interpolation algorithm. Applying the Delaunay triangulation defined earlier, we obtain the implied volatility surface, shown in Figure 5.3 along with its contour plot. From this surface we can easily extract (numerically) the gradients required for the local volatility formula.

![Image of implied volatility surface and contour plot](image_url)

Figure 5.3: Implied volatility surface (left) and corresponding contour plot (right) of the function interpolated linearly between the original data points (blue circles) using Delaunay triangulation.

Observing this interpolated surface, we see that its curvature decreases with maturity - the volatility smile becomes less prominent for later maturities - which can also be observed in the provided data, shown in Appendix A.

As we stated before in section 4.1, from the implied volatility surface we should generate a grid of local volatilities, from which we will obtain the local volatility surface. This grid was obtained by defining some limits on the strike prices and maturities, with $K_{\text{min}}$ and $K_{\text{max}}$ being the smallest and largest
strikes in the grid, with intervals $\Delta K$ between them, and with $T_{\text{min}}$ and $T_{\text{max}}$ being the smallest and largest maturities, with intervals $\Delta T$. The values for these quantities that we used throughout this section are shown in Table 5.6.

Table 5.6: Parameters used in the interpolation section of Dupire’s model.

The resulting local volatility surface is represented in Figure 5.4.

![Local volatility surface](image1.png)

![Contour plot](image2.png)

Figure 5.4: Local volatility surface (left) and corresponding contour plot (right) of the function obtained with Dupire’s formula (eq.(3.27)) from the interpolated implied volatility surface in Figure 5.3.

Though we can’t obtain any theoretical results, due to a lack of closed-form solutions in this model, we are able to simulate stock prices using the method described in section 4.3.1 and with them obtain the option prices. The results of these simulations are shown in Figure 5.5, along with the confidence bands and the original market data. To prevent volatilities from becoming too high, we implemented a maximum cutoff value of $\sigma_{\text{max}}=1.5\text{yr}^{-1/2}$, limiting the volatilities sampled from the surface.
Figure 5.5: Implied volatility functions (light-blue dot-dashed) simulated with Monte Carlo under Dupire’s local volatility model with their corresponding 95% confidence band, plotted against the original market data (crosses).

As before, we now see the very large confidence bands for very low strikes. The cause of this behavior was identified on the constant volatility model (with independent fits). We can also observe the large confidence bands for high strikes in the earliest maturities, which has also already been discussed.

The great improvement of Dupire’s model over the constant volatility model is the presence of the implied volatility smiles in the simulated implied volatilities. Furthermore, these smiles follow the market data almost perfectly for strikes near \( S_0 \). We can therefore conclude that this model is clearly more adequate than the constant volatility model presented earlier, which is unsurprising.

The simulations shown in the plots of Figure 5.5 can be thought of as slices of a simulated implied volatility surface. Ideally, this surface would look exactly like the one shown in Figure 5.3. However, in the regions where the simulations behave badly (large strikes for early maturities and low strikes), we expect there to be a very high amount of error in the simulations. This simulated surface is shown in Figure 5.6, along with the simulated functions of the earlier plots and the market data. The respective contour plot is also represented.
Figure 5.6: Implied volatility surface (left) and corresponding contour plot (right) simulated with Monte Carlo under Dupire’s local volatility model plotted against the original market data (blue circles) and the simulated functions shown in Figure 5.5 (red dot-dashed lines).

As expected, the amount of error is quite overwhelming in the regions where the Monte Carlo pricer performs badly. For the regions where the strike approaches $S_0$, the picture is quite different, and the simulations closely follow the data, as expected.

For this model we do not show the table with the relative errors of the implied volatilities and prices, as we did for the constant volatility models, for the simple reason that previously we used the theoretical implied volatilities (i.e. red full lines in Figures 5.1 and 5.2) to calculate the relative errors and not the simulated curves (i.e. dot-dashed light blue lines in the same figures) and with Dupire’s model there are no theoretical lines, only simulations.
5.3 Static SABR Model

As we saw before, in the Static SABR model stock prices and volatilities are governed by the stochastic differential equations

\[ dS(t) = rS(t)dt + e^{-r(T-t)(1-\beta)} \sigma(t)(S(t))^{\beta} dW_1(t), \]  
\[ d\sigma(t) = \nu \sigma(t) dW_2(t), \]  
(5.5a)
(5.5b)

with \( \alpha = \sigma(0) \) and where \( W_1(t) \) and \( W_2(t) \) have a constant correlation of \( \rho \).

The closed-form solution, shown in eq.(3.72), enables us to obtain the theoretical implied volatilities of options priced under this model and will be used in the calibration process.

Before calibrating the model to the market data, we should study the influence of each parameter of this model on the shape of the implied volatility curve, to better interpret the results. This influence is represented in Figure 5.7, where we plot the theoretical function while varying one parameter at a time, keeping all the others constant, thus directly observing that parameter's influence.

We should note that the influence of the parameters is more complicated than we show here. On the one hand, their impact depends on the maturity. However, for this effect to become evident, we would have to repeat all the plots in Figure 5.7 for several maturities, which would simply become too cumbersome. On the other hand, the parameters have combined effects on the curve shape. These influences would be quite difficult to represent. Furthermore, they are discussed in the original article by Hagan [Hagan et al., 2002], and will, for these reasons, not be discussed here. That being said, we can still have a general view of each parameter's impact on the curve.
Figure 5.7: Dependence of the implied volatility curve on each of the Static model SABR parameters. The default parameters used were $S_0 = 1\, \text{€}$, $T = 42$ days and $r = 0$. Furthermore, on all plots, except when the dependence on a parameter is represented, the parameters used were $\alpha = 0.2\, \text{yr}^{-1/2}$, $\beta = 1$, $\rho = -0.5$ and $\nu = 1.5\, \text{yr}^{-1/2}$.

(a) Dependence on $\alpha$
(b) Dependence on $\beta$
(c) Dependence on $\rho$
(d) Dependence on $\nu$

In Figure 5.7(a) we see that the parameter $\alpha$, which corresponds to the initial value of the volatility process, has quite an impact on the implied volatility curve. We can see that this parameter seems to control the height of the curve. This is indeed expected, because the implied volatility and the stochastic (local) volatility are inherently related. Increasing $\alpha$ is expected to shift the volatility process to higher values, thus increasing the resulting implied volatility.

The influence of the parameter $\beta$, which is an exponent in the stock price process, is represented in Figure 5.7(b). The impact of this parameter seems to be almost negligible. Indeed, at a single point in time, the implied volatility curve barely depends on this value, but this parameter becomes very important when time passes and the stock prices change. Hagan et al. [Hagan et al., 2002] show that $\beta$ controls how the curve shifts when the stock prices move: if the stock price increases, the implied volatility curve at that time should shift to the right; for $\beta = 0$, the curve also shifts downwards, whereas for $\beta = 1$ it doesn’t, moving only horizontally. Despite this, because in Static SABR we are only fitting data for a single maturity, this parameter should barely have any influence in the resulting implied volatility function, though it will become quite relevant in the Dynamic SABR model, where maturity is taken into account.
In Figure 5.7(c) is represented the effect of the parameter $\rho$, the correlation between the stock price and the volatility processes. We can see that this parameter impacts the skewness of the implied volatility curve. Because this parameter relates the stock price and volatility, in the case of a negative $\rho$ when the prices increase (decrease), the volatilities decrease (increase), so that options with higher (lower) strikes have lower (higher) associated volatilities. This justifies why we have a lower implied volatility for higher strikes and a higher implied volatility for lower strikes when the correlation is negative. The inverse logic can be applied for the positive $\rho$ curve observed.

Finally, the impact of the parameter $\nu$, the volatility of the volatility process, is shown in Figure 5.7(d). This parameter seems to control the curvature of the implied volatility curve. It should be clear that higher values of $\nu$ result in greater changes in the volatility process, enabling, at times, the volatility to become quite large. This allows the stock price process to evolve quite erratically, thus making it easier for stock prices to reach higher values, making high strike options more valuable. This effect pushes their implied volatility upwards. The inverse effect also holds and a low $\nu$ will force the stochastic volatility process to become quite limited, preventing the stock prices from changing too much, and restraining them from reaching high strikes, pulling the implied volatility curve downwards.
We now present the results of the calibration as well as the simulations in Figure 5.8.

We now analyze the results of this model. Observing the plots in Figure 5.8 we see that the theoretical function (full red line), obtained by the closed form solution of the Static SABR model, fits the data extremely well through the whole range of strikes and for each of the maturities, which is further

![Graphs for different maturities](image)

(a) $T = 21$ days  
(b) $T = 42$ days  
(c) $T = 63$ days  
(d) $T = 126$ days

Figure 5.8: Implied volatility functions (red lines) fitted independently to the implied volatility data (crosses) for different maturities under the static SABR model, plotted with their respective Monte Carlo simulated functions (light-blue dot-dashed lines) along with their 95% confidence bands (blue region).

As mentioned before, the Static SABR model is only expected to work for data on options with a single maturity. For this reason, we fitted the model to each maturity independently. The parameters obtained in the calibration for each maturity are shown in Table 5.7.

Table 5.7: Fitted parameters for each maturity (fitted independently) under static SABR model.

We now analyze the results of this model. Observing the plots in Figure 5.8 we see that the theoretical function (full red line), obtained by the closed form solution of the Static SABR model, fits the data extremely well through the whole range of strikes and for each of the maturities, which is further
corroborated by the extremely low cost values in Table 5.7.

Though the model seems to fit almost perfectly to the data, the fits may not be very robust. The reason for this is the fact that we have an extremely small amount of data points (7 for each maturity) for the comparatively large number of parameters used (4 parameters in total). This will cause our model to overfit the data - for such a low amount of data (compared to the high number of parameters) we can find many possible combinations of parameters that fit the data just as well as the parameters found by the optimizer.

As for the simulated functions, we note that they very closely the theoretical curves in the regions around $S_0$, indicating that the Monte Carlo pricer implementation was done correctly. This feature doesn’t hold at the high strike region in the first maturity and the low strike regions of all maturities for the same reasons described earlier.

Examining now the calibrated parameters in Table 5.7 we first note that the parameter $\alpha$ doesn’t seem to vary too much between maturities, which is expected, since it controls the height of the implied volatility curve which doesn’t seem to change too much in the plots. Furthermore, we see that these values are close to what is usually observed in the market.

The parameter $\beta$ appears to change wildly between maturities, though this is unsurprising since, as we saw, this parameter doesn’t significantly affect the shape of the implied volatility function, meaning that different values of $\beta$ would fit the data equally well (i.e. overfitting).

As for the parameter $\rho$, we first note that it is always negative, which is expected from reality. It also seems to decrease with time which is expected for options with stock indices as underlying assets, as we mentioned in subsection 3.6.3.

Finally, the parameter $\nu$ also seems to decrease with time. This should come as no surprise, since the curvature of the implied volatility function is expected to decrease with time, with the function becoming increasingly horizontal, as can be seen from the provided data and as we mentioned in subsection 3.6.3. We should also note that the calibrated $\nu$ is quite large, which means that the volatility process evolves quite erratically.
The data of the fitted implied volatility and its respective option prices, along with their relative errors, can be found in Table 5.8.

Table 5.8: Fitted implied volatilities and respective option prices along with their corresponding relative errors w.r.t. the provided data under the static SABR model.

The phenomenon of high relative errors of the stock price for options with high strikes can be observed here as well, and will not be discussed again.

Furthermore, we can see that the errors in the implied volatilities are, at most, only 4%, which is extremely low, which further corroborates the low cost values shown in Table 5.7.
5.4 Heston Model

The Heston model is defined as

\begin{align}
    dS(t) &= rS(t)dt + \sqrt{\nu(t)}S(t)dW_1(t), \\
    d\nu(t) &= \kappa(\nu - \nu(t))dt + \eta\sqrt{\nu(t)}dW_2(t),
\end{align}

where \( \nu_0 = \nu(0) \) and with \( W_1(t) \) and \( W_2(t) \) having a constant correlation of \( \rho \).

With the closed form solution of the Heston model, shown in eq.(3.33), we are able to find the theoretical prices of options priced under this model, which we can easily convert to implied volatilities. These last will be used in the calibration process.

As we did for the Static SABR model, we first study the influence of each parameter of the Heston model on the shape of the implied volatility curve, represented in Figure 5.9.
Figure 5.9: Dependence of the implied volatility curve on each of the Heston model parameters. The default parameters used were $S_0 = 1 \, \text{€}$, $T = 42$ days and $r = 0$. Furthermore, on all plots, except when the dependence on a parameter is represented, the parameters used were $\kappa = 10 \text{yr}^{-1}$, $\varpi = 0.25 \text{yr}^{-1}$, $\nu_0 = 0.04 \text{yr}^{-1}$, $\eta = 1 \text{yr}^{-1}$ and $\rho = -0.5$.

The parameters $\kappa$, $\varpi$ and $\nu_0$ are inherently related to one another and their influence can only be understood if all are considered at the same time. The parameter $\varpi$ is the mean value of the variance \textit{(not the volatility! $\nu(t) = \sigma^2(t)$)}, $\nu_0$ denotes the initial variance, and $\kappa$ is the mean-reversion rate, which controls how fast the variance tends to its mean value.
If the parameter $\kappa$ is very large, we expect the variance process to converge very fast to its mean value, $\bar{\nu}$. This means that the variance process $\nu(t)$ is not able to change significantly, as it is always pulled strongly towards $\bar{\nu}$, remaining roughly constant around this value. For this reason, options priced with such parameters would have an almost constant volatility, and their implied volatility curve would tend to a horizontal line valued at the square root of $\bar{\nu}$ (i.e. the mean volatility, $\sqrt{\bar{\nu}} = \sigma$).

On the other hand, if $\kappa$ is very small, the parameter $\bar{\nu}$ will barely have any influence on the implied volatility curve, and the variance process is able to change almost without restrain. This means that the parameter $\nu_0$ will have a large impact on the behavior of the variance process. A large $\nu_0$ enables the variance process to reach higher values (because it starts at a higher value) so that the implied volatility of options priced with these parameters is higher. A small $\nu_0$ would have the opposite effect, decreasing the implied volatility.

If we now have a moderate value for $\kappa$, both parameters $\bar{\nu}$ and $\nu_0$ are expected to have some impact on the implied volatility curve.

By examining Figures 5.9(b) and 5.9(c), with a moderate value for $\kappa$, we see that the implied volatility curves increase/decrease as we increase/decrease the parameters $\bar{\nu}$ and $\nu_0$, which is precisely what we expect. If we now look at Figure 5.9(a), we can confirm that a large value for $\kappa$ (orange dot-dashed line) will produce an almost constant implied volatility curve around the square root of $\bar{\nu}$ ($\sqrt{\bar{\nu}} = \sqrt{0.25} = 0.5\text{yr}^{-1/2}$). For small values of $\kappa$ (blue full line), the influence of the parameter $\nu_0$ becomes more apparent - notice that the curve is pulled downwards since $\nu_0$ is lower than $\bar{\nu}$ - , and we no longer see the horizontal implied volatility curve from before, which is also expected.

The parameters $\eta$ and $\rho$ in the Heston model control the volatility of the variance process and the correlation of this process with the stock price process, respectively. They are very much related to the parameters $\nu$ and $\rho$ of the Static SABR process, respectively, and their impact on the implied volatility curve is the same. For this reason, they will not be discussed again here.
In Figure 5.10 we now show the results of the calibration and the simulations under this model.

![Figure 5.10: Implied volatility functions (red lines) fitted simultaneously to the implied volatility data (crosses) for different maturities under the Heston model, plotted with their respective Monte Carlo simulated functions (light-blue dot-dashed lines) along with their 95% confidence bands (blue region).](image)

The values of the calibrated parameters are shown in Table 5.9.

Table 5.9: Fitted parameters for all maturities (fitted simultaneously) under the Heston model.

Examining the plots in Figure 5.10 we see that the theoretical curves fit the data surprisingly well throughout all the maturities. This is especially surprising when we note that the adjustment is made for the entire data set, with all the different maturities, unlike the Static SABR model, which was only fitted for single maturities, which means that the overfitting problem is attenuated.

Analyzing the fitted parameters’ values, we begin by noting that $\kappa$ is quite large, which means that the variance process tends to its mean value $\eta$ quite fast. It also means that the initial variance, $\nu_0$, has almost no influence on the shape of the fitted curves. We note furthermore that the mean variance, $\nu$, corresponds to a mean volatility of $0.2555\text{yr}^{-1/2}$ ($\sqrt{\nu} = \pi$), which is a typical value for volatilities observed
in the market. The same applies to the initial variance, $\nu_0$. As for the correlation parameter, $\rho$, we note that it is negative, which is indeed expected from market behavior. Finally, the volatility of the variance process, $\eta$, is very large, which suggests that this process is very erratic.

Observing now the simulated curves and their respective confidence bands we again see that they fit the closed-form solutions extremely well in the region around $S_0$, indicating that the simulations agree with the predictions of the closed form solutions. The large confidence bands described before for the high strikes and early maturities and for the low strikes can also be found here. Because the phenomenon is the same as before, they will not be described again.

Both the simulated and theoretical implied volatility curves shown in the plots of Figure 5.10 for different maturities can be thought of as slices of implied volatility surfaces (one simulated, another theoretical). Similarly to what we did for the Dupire model, we again represent these surfaces and their respective contour plots in Figures 5.11 and 5.12.

![Figure 5.11: Implied volatility surface (left) and corresponding contour plot (right) of the function fitted simultaneously to the implied volatility data for different maturities under the Heston model, plotted against the original market data (blue circles) and the fitted functions shown in Figure 5.10 (red lines).](image-url)
Figure 5.12: Implied volatility surface (left) and corresponding contour plot (right) of the function simulated using the Monte Carlo method with the fitted parameters shown in Table 5.9, under the Heston model, plotted against the original market data (blue circles) and the simulated functions shown in Figure 5.10 (red dot-dashed lines).

The surfaces and contour plots shown in Figures 5.11 and 5.12 should, ideally, replicate the surface and contour plot shown in Figure 5.3, since these last correspond to the real (interpolated) implied volatility surface. The simulated theoretical surface mimics the real function very well, which is expected, since the fits adjusted greatly to the data. As for the simulated surface, we can see the expected noisy region for the low strikes. The simulations around $S_0$ are very close to the ideal values, though, as we can see from the comparison of the contour plots.
As before, we show in Table 5.10 the implied volatilities and their respective option prices as well as their relative errors.

</table>

Table 5.10: Fitted implied volatilities and respective option prices along with their corresponding relative errors w.r.t. the provided data under the Heston model.

We can see that the relative errors shown in Table 5.10 for the Heston model are higher than those for the Static SABR model, in Table 5.8. This is expected from the comparison of their respective costs and was discussed previously. Not much else can be added that hasn’t been observed and discussed before.
5.5 Dynamic SABR Model

We now consider the Dynamic SABR Model, for which the stock price and volatility processes were assumed to follow

\begin{align}
    dS(t) &= rS(t)dt + e^{-r(T-t)\beta}(S(t))^{\beta\sigma(t)}dW_1(t), \\
    d\sigma(t) &= \nu(t)\sigma(t)dW_2(t),
\end{align}

(5.7a) (5.7b)

with the volatility of the volatility process, \( \nu(t) \), and the correlation between \( W_1(t) \) and \( W_2(t) \), \( \rho(t) \), being two functions of time.

To model these functions, we chose

\begin{align}
    \rho(t) &= \rho_0 e^{-at}, \\
    \nu(t) &= \nu_0 e^{-bt},
\end{align}

(5.8) (5.9)

with \( \rho_0 \in [-1, 1], \nu_0 > 0, a > 0 \) and \( b > 0 \).

The parameters used in the Dynamic SABR model are similar to those used in the Static SABR model and an easy connection can be made between them. Their influence on the implied volatility curve will therefore be the same and, for this reason, they will not be represented again here.

We fitted the Dynamic SABR model to the implied volatility data for all maturities. The fitted theoretical curves (obtained with the closed-form solution in eq.(3.78)) and their simulated counterparts are shown in Figure 5.13.
Figure 5.13: Implied volatility functions (red lines) fitted simultaneously to the implied volatility data (crosses) for different maturities under the dynamic SABR model, plotted with their respective Monte Carlo simulated functions (light-blue dot-dashed lines) along with their 95% confidence bands (blue region).

The calibrated parameters obtained from the fit are shown in Table 5.11.

</tr>
</tbody>
</table>

Table 5.11: Fitted parameters for all maturities (fitted simultaneously) under the dynamic SABR model.

We now consider the adjustments above. Observing the theoretical curves in Figure 5.13 we can see that they fit the market data relatively well, especially for the later maturities.

Analyzing the calibrated parameters in Table 5.11, we begin by noting that the value of $\alpha$ is typical from market observations. As we mentioned previously, the parameter $\beta$ controls how the implied volatility curve shifts when the stock prices move, and the calibrated value indicates that when the stock prices increase, the curve not only shifts to the right but also downwards, though only slightly.

The parameter $a$ being 0 implies that the correlation function, $\rho(t)$, is stuck at $\rho_0$ through time, and the parameter $b$ being very large means that the volatility of the volatility function, $\nu(t)$, goes to 0 extremely
fast (e.g. at the end of the first month, this parameter is only \( \nu(t = 1 \text{ month}) = 0.0578 \text{yr}^{-1} \)). These results are very inconsistent with what we observed in the Static SABR model, where \( \rho \) and \( \nu \) tend (slowly) to zero with time. This seems to suggest that the functions chosen to model these two parameters were not appropriate.

Considering now the simulated curves, we see that they accurately follow the theoretical curves for the regions around \( S_0 \), behaving badly only for the low strike regions and for high strikes with low maturities. This has been observed before in all models and is therefore expected.

As we did for the Heston model, we now present the theoretical and simulated implied volatility surfaces of which the plots in Figure 5.13 are slices. These surfaces and their respective contour plots are shown in Figures 5.14 and 5.15.
Figure 5.14: Implied volatility surface (left) and corresponding contour plot (right) of the function fitted simultaneously to the implied volatility data for different maturities under the dynamic SABR model, plotted against the original market data (blue circles) and the fitted functions shown in Figure 5.13 (red lines).

Figure 5.15: Implied volatility surface (left) and corresponding contour plot (right) of the function simulated using the Monte Carlo method with the fitted parameters shown in Table 5.11, under the dynamic SABR model, plotted against the original market data (blue circles) and the simulated functions shown in Figure 5.13 (red dot-dashed lines).

As stated before, ideally the plots in these two Figures would perfectly mimic the surface shown in Figure 5.3. This obviously doesn't occur. The theoretical surface plot in Figure 5.14 seems to be flatter than the actual surface in the regions around $S_0$ (notice the wider contours in this region) whereas it increases quite abruptly for low strikes. As for the simulated surface in Figure 5.15, in the regions where
the simulations are expected to behave badly, a large amount of error can be observed, as is expected.

Finally, we show in Table 5.12 the implied volatility and price data for the fits presented before, along with their respective relative errors.

Table 5.12: Fitted implied volatilities and respective option prices along with their corresponding relative errors w.r.t. the provided data under the dynamic SABR model.

By analyzing these results, we see that the relative errors increase when compared either with the Heston model or the Static SABR model, which is expected and has already been discussed. Not much else can be added to the analysis of the results.
5.6 Model Overview

To round up all the results shown before and to facilitate comparisons between the models, in Table 5.13 we combine all the costs obtained from the training of all models. For the models where the training was done on each maturity independently (Constant Volatility with independent fits and Static SABR), the values shown denote the sum of the costs for all maturities, \( \Sigma_{Costs} \).

</tr>
</tbody>
</table>

Table 5.13: Comparison between the costs from the calibrated stochastic volatility models.

We begin by noting that under the Constant Volatility model, the cost from the dependent fits is larger than the sum of the costs of the independent fits, which is unsurprising given that when fitting all maturities at once, the optimizer will find the implied volatility that minimizes the cost for all maturities, which will not necessarily be the one that minimizes the cost of each single maturity independently.

Regarding Dupire’s model, as we stated before no closed form solution exists for this model, meaning that we aren’t able to calculate the cost function. However, we saw before that the simulations from the Monte Carlo pricer presented the implied volatility smile phenomenon, suggesting that this model is more adequate than the constant volatility.

As for the Static SABR model, it showed a very significant improvement of 99.3% over the cost of the constant volatility model with independent fits. This is no surprise, since the constant volatility model was expected to fit the data very badly and Static SABR fit it almost perfectly. These costs should be considered carefully, though, due to the overfitting mentioned earlier.

Regarding now the Heston and Dynamic SABR models, we can see that they also present a considerable improvement of 98.0% and 91.3%, respectively, over the constant volatility model with dependent fits, which is also unsurprising for the same reasons as before.

Comparing now the cost resulting from the Heston model with that from Dynamic SABR, we see that even though both models fit the same data on a range of different maturities, Heston outperforms the Dynamic SABR quite significantly. This is further corroborated by the comparison of the theoretical functions in Figures 5.10 and 5.13, from which it is clear that the Heston model’s curves better fit the data.

Finally, we can compare the sum of the costs from Static SABR with the costs from both Heston and Dynamic SABR models. To this regard we can say that the fact that we have a significantly lower cost for Static SABR model is unsurprising since the calibration performed under this model was done for multiple maturities, independently, meaning that a better fit is possible, at the expense of the aforementioned overfitting.
5.7 Barrier Options

Having trained all the models, we are now able to use our results on a slightly modified Monte Carlo method to price Barrier options. This has been described before in subsection 4.3.2 along with all the expected shortcomings.

We priced several Barrier options with different barrier levels, using all the different models described before. In these simulations we used a single maturity of 42 days and the calibrated parameters for each of the models, shown earlier in their respective tables. The results of these simulations are shown in Figure 5.16. For comparison, we also simulated some European option contracts, also represented in Figure 5.16.
Figure 5.16: Option price curves of simulated European call options (light blue dot-dashed lines) and Barrier call options with barrier levels $B = 1.05\,€$ (red full line), $B = 1.1\,€$ (orange dashed line) and $B = 1.25\,€$ (purple dotted line) under each of the models previously studied, for options with a maturity of 42 days.
Analyzing the results of Figure 5.16, we first note that, as expected, when we increase the barrier level the option price decreases. This is indeed observed in all models' simulations, and its cause has been explained before, in section 2.1.2.

Possibly the most striking result that we can observe is just how different the price curves are for the simulated barrier options across the models. As an extreme example, we can note that the curve for the Barrier option with barrier level $B = 1.1 \, \text{€}$ under Dupire's model is actually higher than the curve with barrier level $B = 1.05 \, \text{€}$ under Heston's model, which should never occur. To explain this phenomenon, we can begin by noting that volatility is particularly important in barrier options. A higher volatility translates into a higher probability of the barrier being surpassed and thus a higher chance of activating the option. Because each model produces a different volatility behavior, we expect the prices of barrier options to also be very different. Furthermore, we should also note that the models were calibrated on European options. Indeed, when we compare all the European option price curves (blue dot-dashed lines) we can clearly see that they are the same across all models. Thus, we can conclude that even though the models agree when pricing European options (as they should, since they were all calibrated on the same data set), they don't necessarily agree on the prices of Barrier options.

A more in-depth study is required to verify which model produces the most accurate Barrier option prices, but additional data would be required and this study is out of the scope of this work.
5.8 Pitfalls Found in Implementation

During the implementation of all the models, some pitfalls were found. They were mostly solved, or at least mitigated, and the models were able to perform as expected, as we saw in the previous section. For future reference, and to prevent other researchers from repeating the same mistakes, we now summarize not only the pitfalls observed but also their causes and how we were able to solve them or at least reduce their impact.

5.8.1 Dupire Model

While implementing the Dupire model we noticed that the local volatility surface produced by the model was heavily dependent on the chosen interpolation method. Moreover, we found that it was particularly sensitive to the intervals $\Delta K$ and $\Delta T$ chosen in the interpolation. If chosen to be too large, the gradients wouldn’t be able to capture the surface curvature and the local volatility surface would look unrealistic. If chosen to be too small, because we used Delaunay’s triangulation method as interpolation, which creates triangular planes between three points, the second derivative would be (wrongly) zero if $K$, $K + \Delta K$ and $K - \Delta K$ were all evaluated inside the same triangular plane, which is bound to be true for the majority of points if $\Delta K$ is small enough. Thus, the intervals $\Delta K$ and $\Delta T$ have to be chosen very carefully for the model to work properly.
As an example, in Figure 5.17 we show how different choices for \( \Delta K \) affect the local volatility surface.

Figure 5.17: Influence of \( \Delta K \) on the local volatility surface.

As we can see, both surfaces look highly unrealistic, which serves to demonstrate the severity of choosing inadequate values for \( \Delta K \) and \( \Delta T \).

There exist two possible alternatives to solve this problem. On the one hand, we could significantly increase the size of our data set. This would ensure that the size of the triangular planes from Delaunay’s triangulation is small enough for the numerical derivatives to produce realistic results, even for small values of \( \Delta K \) and \( \Delta T \). The problem with this approach is the fact that more data isn’t always available, and this alternative may not always possible. The other possible path, which was the one implemented, is to test several values for the intervals and observe which of them produces the most realistic gradients and the most realistic local volatility surface. This alternative has the caveat that the choice for the intervals is very subjective and that we lose a great deal of robustness because an interval that is appropriate for a given data set might perform poorly on other data sets.
5.8.2 Heston Model

In the Heston model, we need to evaluate some integrals to find the closed-form solutions of call prices (eqs. (3.34) and (3.35)). These integrals are evaluated between 0 and ∞, and, because they are not analytically solvable, they have to be calculated numerically. We thus obviously need to define some upper limits for the integrals, since numerical integration until ∞ is impossible. Cui et al. [Cui et al., 2017] showed that usually these integrals only have to be evaluated until ≈100, because the integrands decrease fast enough that they become negligible after this point. During our implementation, this threshold proved to be insufficient when we evaluated the integrals for the earlier maturities with strikes far below and far above $S_0$. For such regions, some erratic oscillating behavior was found, which we represent in Figure 5.18. This behavior was not described by Cui et al. possibly because they didn’t study the implied volatility curve for such high and low strikes.

This problem was solved simply by increasing the upper integration limits to 400, for which the oscillating behavior disappeared.

5.8.3 SABR Model

One problem related to the SABR models is the fact that stock prices might become negative, which is clearly absurd. This event is very rare and was usually only found in one of the simulated paths out of 100,000. The reason why this problem only occurred for the SABR models and wasn’t observed in Heston is due to the fact that the volatility process in the former is not mean reverting. This detail enables the volatility process to evolve without restrain. If the volatility process becomes extremely large, the jumps in the stock price process become equally extremely large. In the limit, it is perfectly possible that one of these jumps decreases the stock price process past zero. For the Heston model this problem is
not observed because the volatility process (we used the variance process, but they are equivalent) is
mean-reverting, so that the volatility doesn’t evolve unrestrained and thus the prices don’t evolve too
erratically.

This negative price shortcoming is more problematic in the SABR model because, in the stock price
process, one of the terms is a stock price with an exponent \( \beta \). If \( \beta \neq \{0, 1\} \) and \( S(t) < 0 \), the resulting
\( S(t + \Delta t) \) will become imaginary, and the whole pricing procedure fails.

To solve this problem, we simply cut the negative stock price paths to zero by applying the function
\( \max[S(t), 0] \), preventing them from becoming negative.

5.8.4 Other Problems

During the implementation we also found that, in the Monte Carlo simulations, updating the volatility
process before the stock price produced results that didn’t match the theoretical predictions in both the
Heston and SABR models.

In other words, if we used

\[
S(t + \Delta t) = \sigma(t + \Delta t). (\ldots) + \ldots,
\]

instead of the correct

\[
S(t + \Delta t) = \sigma(t). (\ldots) + \ldots,
\]

the simulations deviate significantly from the theoretical predictions. This is expected because the whole
correlation mechanism, relating the two stochastic processes through the variable \( \rho \), falls apart when we
use the first formula.

Though this might seem trivial, some care must be taken when implementing the Monte Carlo pricer
to use the updating equations in the correct order.
Chapter 6

Conclusions

Volatility is one of the most important subjects in all of quantitative finance, due not only to its impact on the prices of options but also to its elusiveness. In this thesis we studied some of the models most used to forecast this variable.

We began by implementing Dupire’s local volatility model, a non-parametric model which assumes that volatility is a deterministic function of the stock price and the option’s time to maturity. This dependence must be determined by interpolating some real option data, for which we used Delaunay’s triangulation.

We also studied Heston and Static/Dynamic SABR stochastic volatility models, which, as the name implies, assume that volatility itself is a stochastic variable, correlated with the stock price. These models are particularly famous due to their closed form solutions that enable us to easily calibrate them, i.e. find the values of the model variables that best fit the data. This calibration was done using a weight function and the CMA-ES optimization algorithm.

Having trained all models, we input them into a numerical pricer, using the Monte Carlo method to estimate the option prices under each model, which we then compared to the real data, for validation. We also benchmarked each of these models against the simpler model of constant volatility, as assumed by Black and Scholes. Finally, adapting the Monte Carlo pricers we were also able to price Barrier options.

6.1 Achievements

Regarding the stochastic volatility models, we saw that their theoretical predictions (obtained with the respective closed form solutions) accurately followed real European call option prices, even for deep in- and out-of-the money options. For data on a single maturity, the Static SABR model clearly performed best, as is verified by the observed low value of the cost function observed with this model, though some overfitting is expected to have occurred. It also vastly outperforms the constant volatility model, which was unsurprising. When dealing with multiple maturities, the Heston model performed better than Dynamic SABR, though both models outperform the constant volatility model.

For near-the-money strikes (i.e. \( K \sim S_0 \)), the Monte Carlo simulations of all stochastic volatility
models seemed to match both the data and the theoretical predictions, suggesting that the simulations were working properly.

As for Dupire’s local volatility model, for which no theoretical predictions were available, we observed that for near-the-money options the predictions obtained with the Monte Carlo simulations followed the real data very closely.

On all Monte Carlo simulations we also observed some divergence for options with lower strikes, which we were able to explain using the Greek Vega and the relative change of the stock price w.r.t. volatility. One other divergent behavior was found in options with very high strikes and short maturities, which we linked to the low number of simulated paths that are able to reach such strikes in the Monte Carlo simulations.

We were then able to price barrier options by adapting the Monte Carlo algorithm, though we weren’t able to validate our results due to a lack of data for such contracts. This achievement serves to prove that pricing Exotic options with our methods is possible.

In conclusion, we may say all models greatly surpass the constant volatility model, providing results that better match real world data. However, great care should be employed when applying the calibrations to Monte Carlo pricers, particularly for deep in-of-the-money call (or deep out-of-the-money put) options, since the results might diverge.

6.2 Future Work

Despite the good results obtained with the models, there is still much room for improvement. In particular, a lot could still be done to improve the Monte Carlo pricers: first, implementing importance sampling on the simulated paths could significantly reduce the number of simulations required to produce each prediction, thus reducing computation time (this has been done for the Heston model in Stilger [Stilger, 2015]). Secondly, we could use the antithetic variates method to reduce the variance of the simulations. Finally, we could use low-discrepancy sequences, such as Sobol sequences [Sobol’, 1967], in the random number generator used at each simulation step of the Monte Carlo method.

Regarding the models, we could also study the mean-reverting version of the Static SABR model, which prevents the volatility from becoming negative or exploding to very large results. Some different functions for \( \rho(t) \) and \( \nu(t) \) could also be considered, besides the ones we used.

Finally, some study on how each model influences the Greeks of the options would also be quite interesting and useful.

Option Market Data

Here, we present data for European options, which we will use to train and validate the models presented in this thesis. For data compliance reasons, the strike prices were normalized by the initial stock price i.e. $K \rightarrow K/S_0$ so that the original strike prices are inaccessible. Suffice it to say that the underlying asset of the options here represented is a stock index, i.e. a weighted average of the prices of some selected stocks (e.g. PSI-20 (Portugal)).

The data provided pertains to the options’ implied volatilities. We can easily obtain their prices from these values using eq.(3.5). The converted prices of call European options are also shown below.

The number of days here denoted correspond to trading days (i.e. days where exchanges are open and trading occurs) so that one month corresponds to 21 days and one year to 252.

CMA-ES Algorithm Formulas

Here we present the formulas required for the calculation of the mean vector, \( \mathbf{m} \), and the covariance matrix, \( \mathbf{C} \), to be used, at each iteration of the CMA-ES optimization algorithm, on the multivariate normal distribution

\[
N(\mathbf{x}; \mathbf{m}, \mathbf{C}) = \frac{1}{\sqrt{(2\pi)^D |\det \mathbf{C}|}} \exp \left( -\frac{1}{2} (\mathbf{x} - \mathbf{m})^T \mathbf{C}^{-1} (\mathbf{x} - \mathbf{m}) \right). \tag{B.1}
\]

We will directly follow the steps shown in [Dilão and Muraro, 2013]. For a more in-depth explanation of the algorithm, refer to the cited article.

B.1 The Optimization Algorithm

B.1.1 Initialization

We initialize the algorithm by setting the first mean vector, \( \mathbf{m}^{(0)} \), to some initial guess, \( \theta_0 \), and the covariance matrix to the unit matrix, \( \mathbf{C}^{(0)} = \mathbf{I} \).

B.1.2 Sampling

We sample \( \lambda \) points, \( \mathbf{y}^{(1)}_i, i = 1, \ldots, \lambda \), from a multivariate normal distribution \( N(\mathbf{x}; \mathbf{0}, \mathbf{C}^{(0)}) \), generating the first candidate solutions

\[
\mathbf{x}^{(1)}_i = \mathbf{m}^{(0)} + \sigma^{(0)} \mathbf{y}^{(1)}_i, \quad i = 1, \ldots, \lambda, \tag{B.2}
\]

where \( \sigma^{(0)} = 1 \).

B.1.3 Classification

The candidate solutions are ordered based on their cost function, such that we denote \( \mathbf{x}^{(1)}_{1:\lambda} \) as the \( \lambda \)-th best classified point from the set \( \mathbf{x}^{(1)}_1, \ldots, \mathbf{x}^{(1)}_{\lambda} \). In other words, \( \text{Cost}(\mathbf{x}^{(1)}_{1:\lambda}) \leq \text{Cost}(\mathbf{x}^{(1)}_{2:\lambda}) \leq \ldots \leq \text{Cost}(\mathbf{x}^{(1)}_{\lambda:\lambda}) \).
B.1.4 Selection

From the ordered set \(x_{i_A}^{(1)}\) we choose the first \(\mu\) data points (with the lowest cost) and discard the others. We then define the weights \(\omega_i\) as

\[
\omega_i = \left(\frac{\log \left(\frac{\mu + 1/2}{2}\right)}{\sum_{i=1}^{\mu} \log \left(\frac{\mu + 1/2}{2}\right)}\right), \quad i = 1, \ldots, \mu. \tag{B.3}
\]

As an alternative we could also use \(\omega_i = 1/\mu\).

B.1.5 Adaptation

We are finally able to calculate the new mean vector and covariance matrix using

\[
\langle y^{(k)} \rangle_w = \sum_{i=1}^{\mu} \omega_i x_{i_A}^{(k)}, \tag{B.4}
\]

\[
m^{(k)} = m^{(k-1)} + \sigma^{(k-1)} \langle y^{(k)} \rangle_w = \sum_{i=1}^{\mu} \omega_i x_{i_A}^{(k)}, \tag{B.5}
\]

\[
p^{(k)}_c = (1 - c_c)p^{(k-1)}_c + \sqrt{c_c(2 - c_c)\mu_{eff}} \left(C^{(k-1)}\right)^{-1/2} \langle y^{(k)} \rangle_w, \tag{B.6}
\]

\[
\sigma^{(k)} = \sigma^{(k-1)} \exp \left(\frac{c_c}{d_c} \left(\frac{\|p^{(k)}_c\|}{E^*} - 1\right)\right), \tag{B.7}
\]

\[
p^{(k)}_c = (1 - c_c)p^{(k-1)}_c + h^{(k)}_c \sqrt{c_c(2 - c_c)\mu_{eff}} \langle y^{(k)} \rangle_w, \tag{B.8}
\]

\[
C^{(k)} = (1 - c_1 - c_\mu)C^{(k-1)} + c_1 \left(p^{(k)}_c \left(p^{(k)}_c\right)^T + \delta \left(h^{(k)}_c\right)C^{(k-1)}\right) + c_\mu \sum_{i=1}^{\mu} \omega_i x_{i_A}^{(k)} \left(y_{i_A}^{(k)}\right)^T, \tag{B.9}
\]

where we define

\[
\mu_{eff} = \left(\sum_{i=1}^{\mu} \omega_i^2\right)^{-1}, \tag{B.10}
\]

\[
c_c = \frac{4 + \mu_{eff}/D}{D + 4 + 2\mu_{eff}/D}, \tag{B.11}
\]

\[
c_\sigma = \frac{\mu_{eff} + 2}{D + \mu_{eff} + 5}, \tag{B.12}
\]

\[
d_\sigma = 1 + 2 \max \left(0, \sqrt{\frac{\mu_{eff} - 1}{D + 1}} - 1\right) + c_\sigma, \tag{B.13}
\]

\[
c_1 = \frac{2}{(D + 1.3)^2 + \mu_{eff}}, \tag{B.14}
\]

\[
c_\mu = \min \left(1 - c_1, \frac{2\mu_{eff} - 2 + 1/\mu_{eff}}{(D + 2)^2 + \mu_{eff}}\right), \tag{B.15}
\]

\[
E^* = \frac{\sqrt{\sqrt{\left(D+1\right)}}}{\Gamma\left(\frac{2}{3}\right)}, \tag{B.16}
\]

96
\[ h^{(k)}_\sigma = \begin{cases} 
1, & \text{if } \frac{\|p^{(k)}\|}{\sqrt{1-(1-cc)}} < \left( 1.4 + \frac{2}{D+1} \right) E^*, \\
0, & \text{otherwise} 
\end{cases} \tag{B.17} \]

\[ \delta \left( h^{(k)}_\sigma \right) = \left( 1 - h^{(k)}_\sigma \right) cc \left( 2 - cc \right), \tag{B.18} \]

\[ \left( C^{(k)} \right)^{-1/2} = B \left( D^{(k)} \right)^{-1} B^T, \tag{B.19} \]

with \( D \) corresponding to the number of parameters of the model (i.e. the dimensions of the sample space) and we define \( p^{(0)}_\sigma = p^{(0)}_c = 0 \).

These steps are repeated until the termination criterion is met.
